Summary

Elevated primary production due to eutrophication of e.g. marginal seas like the Black Sea or the Baltic Sea leads to declining oxygen (O_2) concentrations and ultimately to anoxic conditions in and above sediments. The degradation of organic matter in the absence of O_2 by sulfate reducing bacteria fosters the accumulation of toxic sulfide (H_2S) in marine basins, also called “dead zones”. The reoxidation of H_2S has been observed in the pelagic redoxcline of the Black Sea in the absence of O_2 , nitrate (NO_3^-) and light. In the respective water depth of H_2S removal, chemoautotrophic bacteria were fixing carbon dioxide (CO_2), which raises the question how these organisms generate energy for cellular activity. In this study two new species of the genus *Sulfurimonas*, namely *S. marisnigri* and *S. baltica* are described, originating from the Black Sea and the Baltic Sea, respectively. *S. marisnigri* and *S. baltica* reduce manganese oxide (MnO_2) with H_2S , elemental sulfur (S^0), thiosulfate ($S_2O_3^{2-}$) and hydrogen (H_2) as electron donors. The utilization of reduced sulfur compounds for the reduction of Mn was suggested since the late 1980s, but evidence was missing until now. *S. marisnigri* oxidizes H_2S and $S_2O_3^{2-}$ to SO_4^{2-} , thereby reducing the particulate MnO_2 to dissolved reactive Mn (putative Mn^{3+}) and Mn^{2+} , which ultimately precipitates as a Ca-rich manganese carbonate, here referred to as $Mn(Ca)CO_3$. It is hypothesized, that the energy metabolism of *S. marisnigri* is altering the chemical boundary conditions at the Mn particle surface, which fosters the authigenesis of $Mn(Ca)CO_3$ at the surface of MnO_2 particles, which was also observed in natural habitats, but the mechanism of formation is still under debate.

The H_2S oxidation rate per cell of *S. marisnigri* in the presence of MnO_2 was estimated and integrated into a numerical model to reconstruct the H_2S profile in the water column of the Black Sea. It is shown that the shape of the H_2S concentration profile and the depth of the ultimate removal of H_2S were depending on high local oxidation rates coinciding with the abundance of *Sulfurimonas* and the expression of the sulfide:quinone oxidoreductase gene

(*sqr*). The formation and maintenance of pelagic redoxclines with a separation of O₂ and H₂S of several meters is discussed with the Black Sea as an example.

S. marisnigri and *S. baltica* were cultivated along with the closely related species *S. gotlandica*. Potential electron acceptors and electron donors for growth, assimilatory C and N metabolism as well as the influence of the abiotic parameters temperature, salinity, pH and O₂ on growth were investigated. The results of these growth experiments and the genomic sequence data of *S. marisnigri* were discussed in comparison to other cultured species of the genus. As an example, it appeared that *S. marisnigri* and *S. baltica* are the first N₂ fixing strains of the genus, despite ammonia (NH₄⁺) is usually available in sufficient amount in their natural habitat.

The results of this thesis showed the existence of a bacterial metabolism connecting the marine Mn and S cycles with implications on the water column biogeochemistry of euxinic basins. Further, the precipitation of Mn(Ca)CO₃ in pure culture experiments might offer a plausible explanation for sediment layers rich in Ca-rich manganese carbonate, which is discussed and hypothesized.

Zusammenfassung

Erhöhte Primärproduktion aufgrund der Eutrophierung von z.B. Randmeeren wie dem Schwarze Meer oder der Ostsee führen zu sinkenden Sauerstoffkonzentrationen (O_2) und letztendlich zu anoxischen Bedingungen an und in Sedimenten. Der Abbau von organischem Material in Abwesenheit von O_2 durch bakterielle Sulfatreduktion führt zu Anreicherung von giftigem Sulfid (H_2S) in sedimentnahen Wasserkörpern, die auch als "tote Zonen" bezeichnet werden. Die Reoxidation von H_2S wurde in der pelagischen Redoxkline des Schwarzen Meeres in Abwesenheit von O_2 , Nitrat (NO_3^-) und Licht beobachtet. In der entsprechenden Wassertiefe der H_2S Oxidation fixieren autotrophe Bakterien Kohlenstoff-dioxid (CO_2), was die Frage aufwirft, wie diese Organismen metabolisch Energie generieren. In dieser Studie werden zwei neue Arten der Gattungen *Sulfurimonas*, *S. marisnigri* und *S. baltica*, beschrieben, die aus dem Schwarzen Meer bzw. der Ostsee isoliert wurden. *S. marisnigri* und *S. baltica* reduzieren Manganoxid (MnO_2) mit H_2S , elementarem Schwefel (S^0), Thiosulfat ($S_2O_3^{2-}$) und Wasserstoff (H_2) als Elektronendonatoren. Die Verwendung von reduzierten Schwefelverbindungen zur Reduktion von Mn wurde seit den späten 1980er Jahren vermutet, jedoch fehlten bis jetzt Beweise aus Kultivierungen. *S. marisnigri* oxidiert H_2S und $S_2O_3^{2-}$ zu SO_4^{2-} , wodurch das partikuläre MnO_2 zu gelöstem reaktivem Mn (Mn^{3+}) und Mn^{2+} reduziert wird, das schließlich als Ca-reiches Mangancarbonat ausfällt und in dieser Arbeit als $Mn(Ca)CO_3$ bezeichnet wird. Es wird diskutiert, dass der Energiestoffwechsel von *S. marisnigri* die chemischen Parameter an der Partikeloberfläche verändert und die Authigenese von $Mn(Ca)CO_3$ an der Oberfläche von MnO_2 -Partikeln fördert.

Die H_2S -Oxidationsraten pro Zelle von *S. marisnigri* in Gegenwart von MnO_2 wurde bestimmt und in ein numerisches Modell zur Berechnung des H_2S Profils des Schwarzen Meeres integriert. Dabei wird gezeigt, dass die Form des H_2S Profils und die Tiefe der endgültigen Entfernung von H_2S von hohen lokalen Oxidationsraten abhängen, die mit der Häufigkeit von *Sulfurimonas* und der Expression des Sulfid:Quinone Oxidoreduktase-Gens

(*sqr*) zusammenfallen. Anhand dieser Ergebnisse wird die Bildung und Aufrechterhaltung von pelagischen Redoxklinen mit einer Trennung von O₂ und H₂S von mehreren Metern am Beispiel des Schwarzen Meeres diskutiert.

S. marisnigri und *S. baltica* sowie die nah verwandten Art *S. gotlandica* wurden kultiviert. Potentielle Elektronenakzeptoren und Elektronendonatoren, die Assimilation von C und N, sowie der Einfluss der abiotischen Parameter Temperatur, Salzgehalt, pH-Wert und O₂ auf das Wachstum der drei Stämme wurden untersucht. Die Ergebnisse dieser Wachstumsexperimente und die genomischen Sequenzdaten von *S. marisnigri* wurden im Vergleich zu anderen kultivierten Arten der Gattung diskutiert. Beispielsweise scheinen *S. marisnigri* und *S. baltica* die ersten N₂-fixierenden Stämme der Gattung zu sein, obwohl Ammonium (NH₄⁺) in ausreichender Menge in ihrem natürlichen Lebensraum vorhanden ist.

Die Ergebnisse dieser Arbeit zeigen die Existenz eines bakteriellen Metabolismus, der die marinen Mn- und S- Zyklen verbindet und Auswirkungen auf die Wassersäulenbiogeochemie von euxinischen Systemen hat. Darüber hinaus könnte die Ausfällung von Mn(Ca)CO₃ eine plausible Erklärung für Ca-reiche Mangancarbonat-haltige Sedimentschichten liefern.

1 Introduction

The conversion of inorganic nutrients like carbon dioxide (CO₂) or ammonia (NH₄⁺) into organic molecules, organic matter or living matter like DNA or amino acids is called primary production. With carbon as the most important element as an example, the fixation of CO₂ and the conversion into organic molecules by light dependent oxygenic photosynthesis can be expressed as shown in Eq. 1.1.

The assimilation of inorganic carbon as carbon source is called autotrophy and can also be light independent (dark CO₂ fixation). In this process, carbon is reduced from a +IV oxidation state in CO₂ to 0 in the organic molecule [CH₂O], which is crucial to form C-C polymers, thereby accepting 4 mole of electrons (e⁻) per mole of CO₂ fixed. The degradation of organic carbon back to the inorganic nutrient CO₂ is called respiration and is performed by organotrophic organisms. The dissimilatory respiration of organic carbon to CO₂ in return is releasing 4 mole of e⁻, transferred to an electron acceptor, which is oxygen (O₂) in the so called oxic respiration.

O₂ solubility in sea water is limited and depending on temperature as well as salinity and ranges from 456 μM (0 °C; 0 g/kg) to 231 μM (20 °C; 35 g/kg) (Ramsing & Gundersen, 2011). The depth profile of dissolved O₂ in the ocean or marginal seas is typically uniform and close to saturation in the mixed surface water layer and decreases below due to the oxic remineralization of sinking organic matter (Stramma et al., 2008). In systems with hampered deep water ventilation, i.e. lacking O₂ transport into deeper parts of the system, e.g. due to density stratification, the O₂ demand for the remineralization of organic matter can exceed the ambient concentrations of O₂ easily, which leads to low O₂ concentrations and ultimately to anoxia, with far reaching consequences for higher organisms. In the course of climate change, rising water temperatures decrease the O₂ solubility and hampers thermohaline circulation,

thereby reducing the amount of O_2 transported to the deep ocean (Schmidtko et al., 2017). Likewise, increased nutrient input from excessive agriculture stimulates primary production and ultimately O_2 demand in deeper waters (Diaz & Rosenberg, 2008).

In the absence of O_2 , organic matter is degraded anaerobically by the utilization of alternative electron acceptors. Anaerobic degradation of organic matter follows a sequence of alternative electron acceptors (Fig. 1) based on the potential energy yield of the respective redox reaction (Froelich et al., 1979) as summarized in Tab. 1. Because the large availability of SO_4^{2-} with about 28 mM in sea water with a salinity of 35 (Jørgensen et al., 2019) exceeds the nano- to micromolar concentrations of nitrate (NO_3^-), MnO_2 and iron (Fe) oxides by orders of magnitude, SO_4^{2-} is the most important electron acceptor for anaerobic organic matter degradation. Consequently, 25 – 50% of the organic carbon may be remineralized by sulfate reducing bacteria in marine shelf sediments in the absence of O_2 (Jørgensen, 1982), despite

Figure 1: From Jørgensen (2000). Pathways of organic matter degradation in the water column and sediment. Degradation of organic matter to low molecular weight biogenic material like sugars, amino acids or fatty acids and finally inorganic compounds like CO_2 , NH_4^+ , HPO_4^{2-} etc. is consuming O_2 and a sequence of alternative electron acceptors as soon as O_2 becomes limited.

Table 1: Adapted from Jørgensen (2000). Data from Thauer et al. (1977), Conrad et al. (1986) and Fenchel & King (1998). Sequence of potential energy yield of organic matter respiration processes from oxic respiration to methanogenesis. ΔG^0 values in kJ mol⁻¹ [CH₂O].

Respiration process	e ⁻ Acc.	Product	ΔG^0 (kJ mol ⁻¹)
<i>Oxic respiration</i>			
[CH ₂ O] + O ₂ → CO ₂ + H ₂ O	O ₂	H ₂ O	-479
<i>Denitrification / Nitrate reduction</i>			
5 [CH ₂ O] + 4 NO ₃ ⁻ → 2 N ₂ + 4 HCO ₃ ⁻ + CO ₂ + 3H ₂ O	NO ₃ ⁻	N ₂	-453
<i>Manganese oxide reduction</i>			
[CH ₂ O] + 3 CO ₂ + H ₂ O + 2 MnO ₂ → 2 Mn ²⁺ + 4 HCO ₃ ⁻	MnO ₂	Mn ²⁺	-349
<i>Iron oxide reduction</i>			
[CH ₂ O] + 7 CO ₂ + 4 Fe(OH) ₃ → 4 Fe ²⁺ + 8 HCO ₃ ⁻ + 3 H ₂ O	Fe(OH) ₃	Fe ²⁺	-114
<i>Sulfate reduction</i>			
2 [CH ₂ O] + SO ₄ ²⁻ → H ₂ S + 2 HCO ₃ ⁻	SO ₄ ²⁻	H ₂ S	-77
<i>Methanogenesis</i>			
CH ₃ COO ⁻ + H ⁺ → CH ₄ + CO ₂	CH ₃ COO ⁻	CH ₄	-28

the low energy yield ($\Delta G^0 = -77$ kJ mol⁻¹ [CH₂O]) compared to aerobic respiration ($\Delta G^0 = -479$ kJ mol⁻¹ [CH₂O]) or Mn reduction ($\Delta G^0 = -349$ kJ mol⁻¹ [CH₂O]) (Tab. 1).

Anaerobic respiration results in the formation of reduced compounds of N, Mn, Fe, S and C; NH₄⁺, Mn²⁺, Fe²⁺, sulfide (H₂S here referred to as \sum H₂S, HS⁻ and S²⁻) and methane (CH₄), respectively (Tab. 1, Fig. 1). Next to the demand for O₂ and the oxidized forms of the above mentioned elements for organic matter degradation, also the reoxidation of the reduced compounds requires oxidation potential. As pointed out above, SO₄²⁻ reduction is by far the most important process for anaerobic organic matter degradation. Consequently, H₂S is a common end product that is toxic to higher organisms even in low concentrations (Evans, 1967). As long as the reoxidation of H₂S (Tab. 2) is equally effective as the concurrent sulfate reduction, H₂S remains undetectable (Jørgensen et al., 2019). Next to an effective reoxidation, H₂S is also trapped in iron mono-sulfide precipitates (FeS) with Fe²⁺ ions, which also prevents the formation of free H₂S and the release out of the sediment (Rickard & Luther III, 2007). As soon as sulfate reduction rates exceed the concurrent reoxidation and binding capacity of the Fe pool, free H₂S will be detectable, which is described as euxinic condition (King, 2004;

Table 2: Electron acceptors for the oxidation of H₂S and the respective potential free energy at standard conditions and pH7 ($\Delta G^{0'}$) per mole H₂S or per electron transferred. Values for the calculation were taken from Thauer et al. (1977) and Stumm & Morgan (1996).

Electron acceptor for H ₂ S oxidation (1 atm, 25 °C, pH7)	$\Delta G^{0'}$ (kJ mol ⁻¹ H ₂ S)	$\Delta G^{0'}$ (kJ mol ⁻¹ e ⁻)
<i>Oxygen</i>		
$\text{HS}^- + 2 \text{O}_2 \rightarrow \text{SO}_4^{2-} + \text{H}^+$	-797	-100
<i>Nitrate (Denitrification)</i>		
$5 \text{HS}^- + 8 \text{NO}_3^- + 3 \text{H}^+ \rightarrow 5 \text{SO}_4^{2-} + 4 \text{N}_2 + 4 \text{H}_2\text{O}$	-744	-93
<i>Manganese oxide</i>		
$\text{HS}^- + \text{MnO}_2 + 3 \text{H}^+ \rightarrow \text{S}^0 + \text{Mn}^{2+} + 2 \text{H}_2\text{O}$	-130	-65
$\text{HS}^- + 4 \text{MnO}_2 + 7 \text{H}^+ \rightarrow \text{SO}_4^{2-} + 4 \text{Mn}^{2+} + 4 \text{H}_2\text{O}$	-478	-60

Rickard & Luther III, 2007). The former sedimentary redoxcline, as the depth boundary to waters with detectable free H₂S, can move into the water column by leakage of H₂S out of the sediment and form a pelagic redoxcline.

Pelagic redoxclines in marine systems are frequently reported from semi enclosed basins and/or water systems with a strong density stratification like the Black Sea (Murray et al., 1989), the Baltic Sea (Grote et al., 2007; Dellwig et al., 2010; Jost et al., 2010), the Cariaco Basin (Taylor et al., 2001), the Saanich Inlet (Zaikova et al., 2010) or the Framvaren Fjord (Mandernack & Tebo, 1999). High nutrient load together with limited ventilation fosters severe accumulation of free H₂S formed by SO₄²⁻ reduction in bottom waters. A lower cellular abundance of 10⁴ - 10⁶ cells mL⁻¹ in pelagic redoxclines compared to 10⁸ - 10¹⁰ cells cm⁻³ (Canfield et al., 2005) in sedimentary redoxclines with accordingly lower reaction rates results in less steep concentration gradients and spreads this zone of intensive element cycling from centimeter to meter scale, allowing high resolution sampling and investigation of the underlying processes. A frequently studied system with a permanent stratified water column and pelagic redox transition zone is the Black Sea.

With a maximum depth of about 2200 m, an area of 4.2 x 10⁵ km² and a volume of 5.3 x 10⁵ km³, the Black Sea is the largest semi enclosed basin in the world (Özsoy & Ünlüata, 1997). Inflow of high saline waters from the Mediterranean Sea through the Bosphorus strait and

inflow of freshwater from rivers causes vertical density stratification due to a shift in salinity from 18 in the freshwater effected surface waters to a salinity of 22 in bottom waters (Dellwig et al., 2012). This density gradient restricts the mixing of the surface waters to a maximum depth between 60 and 80 m water depth, below turbulent diffusion controls fluxes (Murray et al., 1991; Gregg & Yakushev, 2005; Yakushev et al., 2006). The lacking deep water renewal and organic matter degradation by SO_4^{2-} reduction fosters severe accumulation of H_2S in bottom waters starting approximately 50 m below the mixing depth of 60 – 80 m, resulting in the accumulation of 4.6×10^{15} g H_2S due to bacterial SO_4^{2-} reduction in the water body of the Black Sea (Lev N. Neretin, PhD thesis cited in Neretin et al., 2006), leaving just 13% of the total volume with oxic conditions (Özsoy & Ünlüata, 1997). Murray et al. (1989) reported for the first time the existence of a up to tens of meters thick zone lacking O_2 and H_2S , a so called suboxic zone (Fig. 2A).

At the bottom boundary of this suboxic zone at the chemocline, H_2S is disappearing (Fig. 2A and B) more than 10 meters below detectable concentrations of NO_3^- and O_2 (Murray &

Figure 2: Chemical profile, chemolithoautotrophic activity and involved bacterial groups of the Black Sea suboxic zone. A, O_2 and H_2S concentration profiles together with total prokaryotic abundance (from Schulz-Vogt et al., 2019). NO_3^- is approaching 0 at a water depth of 94 m. B, Black Sea suboxic zone together with CO_2 fixation rates. C, Percentage of autotrophic bacteria ($^{14}\text{CO}_2$ -positive cells) of the total bacterial community and importance of the group *Epsilonbacteraeota* (EPS). B and C from Grote et al. (2008).

Figure 3: From Dellwig et al., 2012. Mn cycling across the Black Sea suboxic zone. Cycling of particulate Mn (Mn_{part}) to dissolved (total Mn_{diss}) reactive Mn (dMn_{react}) with active transformation at the upper and lower boundary of the suboxic zone and act as a trap for Mn thereby reaching concentrations of about 9 μM .

of H_2S removal (Fig. 2A and B). Oxidation of H_2S could be coupled to Mn (Fig. 3). Mn is a redox sensitive trace metal, which is particulate in the oxidized form MnO_2 (+IV) and typically dissolved in the reduced ion form Mn^{2+} . The reduced and dissolved Mn^{2+} is transported upwards by turbulent mixing and is reoxidized biologically and chemically with O_2 to particulate MnO_2 at the upper boundary of the suboxic zone, which is again transported via gravitational sinking towards the sulfidic bottom waters (Burdige & Nealson, 1985, 1986; Lewis & Landing, 1991; Tebo, 1991; Tebo et al., 2004). This cycle effectively traps Mn in the suboxic zone and the total concentrations reaches concentrations of about 9 μM (Fig. 3).

Sulfur transformation processes are manifold including inorganic fermentation (disproportionation), oxidation and reduction reactions with a huge variety of electron donors and acceptors as well as redox and equilibrium reactions between sulfur species of different oxidation state (Fig. 4), including abiotic and biotic modes (Siu & Jia, 1999; Jørgensen et al., 2019). The oxidation of H_2S with MnO_2 can be a purely chemical process, but some obser-

Yakushev, 2006; Canfield & Thamdrup, 2009; Schulz-Vogt et al., 2019) raising the question of which compound is oxidizing H_2S . Based on the bacterial abundance in the suboxic zone compared to overlying and underlying waters (Fig. 2A) together with high dark CO_2 fixation rates at and below the chemocline (Fig. 2B) it could be suggested that autotrophic bacteria are responsible for the oxidation of H_2S . However, phototrophic oxidation of H_2S has been shown to be of minor importance in the Black Sea (Overmann et al., 1992) and the established electron acceptors for bacterial H_2S oxidation, NO_3^- and O_2 , are absent in the respective depth

variations speak up against a pure abiotic scenario in the water column of the Black Sea. The abiotic reaction is reported to be fast and complete within minutes in chemical experiments with high concentrations of both reactants (>0.5 M MnO_2 ; 150 μM H_2S - Burdige & Nealson, 1986). The speed of the chemical H_2S oxidation by MnO_2 in sea water depends on the pH, the surface area of the MnO_2 particle and the concentration of H_2S (Yao & Millero, 1993, 1996; Herszage & dos Santos Afonso, 2003). The products of the chemical H_2S oxidation by MnO_2 in sea water depend on the pH and the ratio between H_2S and MnO_2 (Yao & Millero, 1996; Herszage & dos Santos Afonso, 2003).

Based on these chemical studies elemental sulfur (S^0), thiosulfate ($\text{S}_2\text{O}_3^{2-}$), sulfite (SO_3^{2-}) and SO_4^{2-} are the oxidation products of a chemical oxidation with MnO_2 in sea water, with S^0 as the dominant reaction product. A low MnO_2 to H_2S ratio and higher pH fosters the formation of elemental sulfur as oxidation product (Yao & Millero, 1996; Herszage & dos Santos Afonso, 2003). The speed of the chemical reaction is maximal at pH 5 and decreasing towards lower and higher pH values (Yao & Millero, 1996). At the redoxcline of Black Sea approximately 20 nM MnO_2 and < 5 μM H_2S were reported at near neutral pH (Fig. 2 and 3). Under these conditions elemental sulfur should be the almost exclusive reaction product at the chemocline of Black Sea, but no major accumulation of this or other intermediate compounds have been reported (Jørgensen et al., 1991; Luther III et al., 1991; Glazer et al., 2006). In con-

Figure 4: from Zopfi et al. (2004) modified from Jørgensen et al. (2019). Transformation processes of the important inorganic species of the sulfur cycle. Large black arrow represents sulfate reduction, thin black arrows oxidation reaction and dotted lines disproportions. Dashed lines represent equilibrium reaction to form polysulfides (S_x^{2-}). Mean oxidation state of S are as follows: H_2S (-2), elemental sulfur S^0 (0), thiosulfate $\text{S}_2\text{O}_3^{2-}$ (+2), tetrathionate $\text{S}_4\text{O}_6^{2-}$ (+2.5), sulfite SO_3^{2-} (+4) and SO_4^{2-} (+6).

trast, biological H_2S oxidation by lithotrophic bacteria is typically complete to SO_4^{2-} [e.g. S oxidation coupled to denitrification by *Sulfurimonas gotlandica* GD1 (Grote et al., 2012) or S oxidation coupled to O_2 by *Beggiatoa* sp. (Nelson et al., 1986)] which would explain the absence of accumulating sulfur intermediates.

Even though the reaction of H_2S and MnO_2 is reported to be fast in chemical studies, it is emphasized, that the speed of the reaction is depending on the pH and the concentrations of both reactants. At the redoxcline of the Black Sea, concentrations of H_2S and MnO_2 are low (Fig. 2 and 3) which should result in overall low reaction rates (Yao & Millero, 1993) and should affect the overall concentration profile of H_2S . This was shown by Nelson et al. (1986) in culture experiments (Fig. 5). Depending on the absence (Fig. 5A) or presence (Fig. 5B) of *Beggiatoa*, the depth profiles of O_2 and H_2S were completely different. Biological H_2S oxidation coupled to the reduction of O_2 by *Beggiatoa* sp. is 10,000 to 100,000 times faster compared to the corresponding chemical reaction (Jørgensen & Revsbech, 1983). These high reaction rates result in the increased fluxes of both reactants (Fig. 5, Jørgensen & Revsbech,

Figure 5: From Nelson et al. (1986). Depth profile of O_2 and H_2S in a marine sediment, either with or without a *Beggiatoa* mat. Without the fast biological H_2S oxidation rates by *Beggiatoa* (B), concentration profiles of the reactants O_2 and H_2S overlap in control sediment cores (A). Higher oxidation rates did also result in steeper concentration gradients and thereby in higher fluxes of both, H_2S and O_2 .

1983; Nelson et al., 1986) and to a pronounced change from a curved (Fig. 5A, abiotic) to a linear concentration gradient (Fig. 5B, biological) of both, O₂ and H₂S. Due to the high reaction rates, the depth horizon of active H₂S oxidation with O₂ is diminished from 6.7 mm (Fig. 5A) to 0.3 mm (Fig. 5B), resulting in the apparently linear concentration gradients in the upper centimeter of the cultivation tube. Similarly, also the oxidation rates of H₂S in pelagic redoxclines will shape the form of the gradient in situ and thus the observed linear concentration gradient (Fig. 2A and B) indicates a fast H₂S oxidation rate in a narrow zone. It can be assumed that the faster the reaction, biological, chemical or both, the smaller the overlap of oxidant and reductant and consequently the more linear the concentration gradient appears in the depth profile.

The reduction of MnO₂ for the degradation of organic matter is known for species of e.g. the genera *Shewanella* and *Geobacter* (Myers & Nealson, 1988; Lovley, 1991) but so far no isolate existed that couples the oxidation of H₂S to the reduction of MnO₂. However, indirect evidence for a bacterially mediated H₂S oxidation with MnO₂ came from marine sediments. Aller & Rude (1988) and King (1990) reported the formation of SO₄²⁻ when MnO₂ was added to anoxic sediment slurries, which was inhibited by the addition of 2,4-dinitrophenol and sodium azide, indicating a biological mode of SO₄²⁻ formation. Interestingly, SO₄²⁻ formation could not be stimulated by the addition of Fe-oxides. Thus, the formation of SO₄²⁻ was unlikely a combination of an abiotic oxidation of H₂S to S⁰ and subsequent bacterial disproportionation to H₂S and SO₄²⁻, because S⁰ would also form with Fe-oxides (Yao & Millero, 1996). In any case, unambiguous evidence for a biologically mediated oxidation of H₂S with MnO₂ can only be drawn from experiments with isolated pure cultures.

In the present work, two new species of the genus *Sulfurimonas* were investigated. The strains *Sulfurimonas marisnigri* and *S. baltica* were enriched and isolated with MnO₂ provided as the sole electron acceptor. With *S. marisnigri*, originating from the lower boundary of the Black Sea suboxic zone, studies on biological Mn reduction coupled to the oxidation of reduced

sulfur compounds, dynamics of Mn and S during the growth phase of *S. marisnigri* and estimations of biological H₂S oxidation rates were done. *S. baltica*, originating from a turbulent redoxcline of the central Baltic Sea after salt water inflow from the North Sea, was cultured as well as *S. marisnigri* and *S. gotlandica* to examine the metabolic potential of the two new isolated strains in comparison to a well-documented species of the genus. Results of the growth experiments from *S. marisnigri* and *S. gotlandica* were further compared and discussed with the annotated genomes of both species.

2 Material and methods

2.1 Preparation of anoxic cultivation medium

The Standard medium for cultivation and experiments, if not mentioned otherwise, was prepared following the technique described by Widdel & Pfennig (1981) based on sulfate free artificial seawater with a salinity of 21, 14, or 10 for *S. marisnigri*, *S. baltica* or *S. gotlandica*, respectively. Artificial seawater of the different salinities was prepared by dissolving the dry chemicals in 1 L of MilliQ water (Tab. 3).

The artificial seawater was filled into a special glass vessel, colloquially called “Widdelkolben”, autoclaved and subsequently cooled under a constant flow of N₂ gas with 10 to 30% CO₂ to purge O₂ to achieve anoxic conditions. After 10 minutes of gas flow, the glass vessel was closed and a slight overpressure was maintained to avoid contamination of air and to speed up the pH adjustment by the formation of carbonic acid. After cooling, the components listed in Tab. 4 were added. Solutions of NaHCO₃ and NH₄Cl were prepared with Ar purged MilliQ water and autoclaved under Ar atmosphere. Components of the trace elements solution SL7 and the vitamin solution are listed in Tab. 5 and 6, respectively. No resazurin was added to the medium because growth of *S. marisnigri* with particle metal oxide electron acceptors was apparently suppressed by the redox indicator.

Table 3: Components of sulfate free artificial seawater with different salinities for the three *Sulfurimonas* strains.

Dry chemical	g L ⁻¹		
	Sal. 21	Sal. 14	Sal. 10
NaCl	17.7	11.8	8.5
MgCl ₂ • 6 H ₂ O	3.2	2.2	1.5
CaCl ₂ • 2 H ₂ O	0.4	0.3	0.2
KCl	0.7	0.4	0.3

Table 4: Solutions added to artificial seawater for the preparation of standard anoxic medium.

solution	mL L ⁻¹
1 M NaHCO ₃	30
100 mM NH ₄ Cl	0.2
Trace elements solution SL7 (Tab.5)	1
10 mM Na ₂ HPO ₄	1
Vitamin solution (Tab.6)	0.42

Further, no reducing agent was added to the standard medium. The pH of the medium was adjusted to approximately 7.5 by the exposure time to the anoxic N₂ gas mixture containing 10 to 30% CO₂. After the pH was reached, the medium was dispensed into 100 mL or 150 mL sterile serum bottles, with a small headspace volume of 10 – 20 mL, which was exchanged by the respective anoxic gas mixture several times and closed with gas tight butyl rubber stoppers. All additions and bottling were performed in a sterile working bench. Bottles were stored in the dark at 10 °C. Substrates were added to the prepared medium before inoculation.

2.2 Preparation of stock solutions

Stock solutions were prepared by adding the respective chemical to anoxic MilliQ water, purged with Ar or N₂, in serum bottles closed with butyl rubber stoppers. Solution and headspace were purged for at least 1 hour with Ar or N₂ gas by penetrating the rubber stopper with two cannulas, one to the ground of the bottle and one to provide a gas outflow. Afterwards, stock solutions were heat sterilized in closed bottles and stored in the refrigerator.

2.2.1 Manganese oxide (MnO₂)

Technical MnO₂ was purchased as powder from Merck (Darmstadt, Germany) and additionally grinded with an agate ball mill. The ground MnO₂ was added to Ar/N₂ purged MilliQ

Table 5: Components of the trace elements solution SL7 from Widdel and Pfennig (1981) filled to 1 L with MilliQ water.

Solution or dry chemical	Added amount
25% HCl	10 mL
FeCl ₂ • 4 H ₂ O	1.5 g
CoCl ₂ • 6 H ₂ O	0.19 g
MnCl ₂ • 4 H ₂ O	0.1 g
ZnCl ₂	0.07 g
H ₃ BO ₃	0.062 g
Na ₂ MoO ₄ • 2 H ₂ O	0.036 g
NiCl ₂ • 6 H ₂ O	0.024 g
CuCl ₂ • 2 H ₂ O	0.017 g

Table 6: Components of the vitamin solution dissolved in MilliQ water.

Vitamin	g L⁻¹
B 12	0.1
Inositol	0.1
Biotin	0.1
Folic acid	0.1
4-Aminobenzoic acid	1
Nicotinic acid	10
d-pantothenate	10
Thiamine	20

water with different final molarities and used as stock solution. Final suspension was again purged with Ar or N₂ as described above and autoclaved under O₂ free atmosphere. Extraction of MnO₂ from the MnO₂ suspension was done with syringes under constant shaking. All experiments shown in this work were conducted with MnO₂ of the same batch.

2.2.2 Elemental sulfur (S⁰)

Elemental sulfur was prepared as colloidal S⁰ according to Blumentals et al. (1990) with a final concentration of approximately 0.4 M or slightly lower due to minimal losses during washing steps. The final suspension was purged with Ar or N₂ as described earlier and applied as a non-sterile suspension to the respective experiments.

2.2.3 Iron oxides

Amorphous FeOOH and goethite (α -FeOOH) were precipitated as described by Lovley & Phillips (1986). The resulting precipitates were washed with Ar or N₂ purged MilliQ water until the salinity decreased below 10, which was measured with a refractometer. The suspensions of amorphous FeOOH and goethite were purged with Ar or N₂ as described above and autoclaved under O₂ free atmosphere.

2.2.4 Sulfide (Na₂S)

Crystals of Na₂S were dissolved in anoxic MilliQ water, transferred into a serum bottle, purged with Ar or N₂ as described above and autoclaved under O₂ free atmosphere.

2.3 Origin of the three *Sulfurimonas* species

2.3.1 *S. marisnigri*

S. marisnigri originates from the Black Sea (44°-16.7586 N and 36°-18.9567 E) at the lower boundary of the suboxic zone ($\sigma_\theta = 16.145$) where H₂S was just detectable [see Fig. 1 in (Henkel et al., 2019)]. Initial water sampling and enrichment was done by Prof. Dr. Heide N. Schulz-Vogt. Water was sampled at the 21th of November 2013 and filled into a gas tight

Figure 6: Dilution to extinction series with MnO_2 and $\text{S}_2\text{O}_3^{2-}$ to isolate *S. marisnigri*. From left to right: sterile control, dilution of $1:10^4$, dilution of $1:10^5$, and dilution of $1:10^6$ from the previous culturing series.

serum bottle. MnO_2 was provided as sole electron acceptor and H_2S was added daily in small amounts out of a Na_2S stock solution resulting in concentrations of 10-20 μM . After this pre-enrichment for the metabolism of interest, cultivation was continued with $\text{S}_2\text{O}_3^{2-}$ instead of H_2S as electron donor in artificial standard medium prepared as described in chapter 2.1. Isolation was performed by repeated series of dilution-to-extinction transfers. Because MnO_2 particles might have harbored bacteria of different species, dilution series were done with the supernatant of a shortly centrifuged sample from the respective previous culturing series. The highest dilution with positive growth as indicated by the change in color was used for dilution and re-cultivation (Fig. 6).

2.3.2 *S. baltica*

Initial water sample was taken by Prof. Dr. Klaus Jürgens at the 14th of June 2016 in the Gotland Basin of the Baltic Sea at station TF271 (57°-9.2 N and 20°-03 E) at a water depth of 220-225 m after salt water inflow from the North Sea in November 2015 and January-February 2016. Culture enrichment and isolation was performed as described for *S. marisnigri*.

2.3.3 *S. gotlandica*

Cryo-preserved culture stocks of *S. gotlandica* GD1^T from 2014 were thawed and re-cultivated in anoxic media as described in chapter 2.1.

2.4 Culture purity of *S. marisnigri* and *S. baltica*

Cultures were inspected with 4',6-diamidino-2-phenylindole (DAPI) stained epifluorescence and phase contrast microscopy. Plating on heterotrophic marine broth agar medium at ambient oxygen conditions and room temperature did not result in the formation of cell colonies. Analysis of 16 S ribosomal RNA (rRNA) sequenced were performed as described below.

2.4.1 16S rRNA sequencing and 16S rRNA clone libraries

For the phylogenetic classification of the Mn reducing isolates from the Black and Baltic Sea, 16S rRNA sequences were analyzed. As an additional indicator for a successful isolation of the respective species, 16S rRNA clone libraries were prepared and sequenced.

DNA extraction

DNA was extracted using QIAamp DNA Mini Kit (Cat. No. 51306) following the manual.

Amplification of the 16S rRNA gene with the polymerase chain reaction (PCR)

PCR was performed using Taq DNA Polymerase (native with bovine serum albumin (BSA) – Thermo Fisher Scientific, Germany). The protocol was as follows using the reagents sent with the Polymerase. A 50 µL PCR was prepared with 32.1 µL of diethyl dicarbonate (DEPC) H₂O; 5 µL 10x PCR buffer; 1 µL BSA; 5 µL MgCl₂; 1 µL 10 mM deoxynucleotides(dNTP)-mix (Thermo Scientific R0192); 2 µL Primer 27f (5'-AGA GTT TGA TCC TGG CTC AG-3'); 2 µL Primer 1492r (5'-GGT TAC CTT GTT ACG ACT T-3') and 0.27 µL Taq Polymerase. To this mastermix 0.5 µL of a DNA template was added. Samples were placed in a thermocycler with the following temperature protocol: 1 min 94 °C; 30x [1 min 94 °C; 1 min 50 °C; 1.5 min 72 °C]; 10 min 72 °C; 10 °C till samples were taken out and stored at minus 20 °C.

Purification of the PCR product

The PCR products were washed using Agentcourt AMpure XP (Beckman Coulter GmbH, Germany) magnetic beads. 72 µL of AMPure Reagent per 50 µL PCR product was added to a

1.5 mL microcentrifuge tube, gently mixed, shortly centrifuged and incubated at room temperature for 5 minutes. The tube was placed in a magnetic bead separator (drawer) until the solution was clear (about 2-3 minutes). The supernatant was discarded, 200 μ L ethanol (80%) were added and the solution was incubated for 30 seconds. This step was done twice while the tube remained in the drawer. The tube was removed from the drawer and placed with an open lid at 37 °C for 10 minutes. 17 μ L TRIS/EDTA (TE) buffer were added, gently mixed, centrifuged briefly and incubated for 2 minutes at room temperature. The tube was again placed in the drawer for 2-3 minutes and 17 μ L supernatant were transferred into a 0.5 mL PCR tube.

Preparation of clone libraries

Purified PCR amplicons were cloned into the vector pSC-A-amp/kan (StrataClone PCR Cloning Kit – competent cells Strataclone SoloPack) following the manual and plated onto ampicillin-containing (10 mg ampicillin per 100 mL lysogeny broth (LB) medium) LB agar plates (17.5 g LB Agar in 500 mL MilliQ) with 40 μ L 2% X-galactosidase (X-Gal) on top. A 96 well microtiter plate with ampicillin-containing LB agar was picked. Clones were sequenced (LGC, Germany) forwards and backwards using vector primers T3 and T7prom.

Sequence analysis

The sequence reads were analyzed with SeqMan (Seqman II 5.06, DNASTAR Inc.). Sequences were quality trimmed with high stringency, quality checked by eye, assembled and cut with 27f and 1492r primers. Sequence data from the clone library of *S. marisnigri* was deposited at the Genbank sequence database from NCBI (refs. MF563385-MF563475).

2.5 Genome sequencing of *S. marisnigri*

2.5.1 DNA isolation

S. marisnigri was cultivated with $\text{S}_2\text{O}_3^{2-}$ as electron donor and NO_3^- instead of MnO_2 as electron acceptor to avoid negative interference of high Mn particle loads on DNA isolation and downstream application. About 4 L of a grown *S. marisnigri* culture were filtered onto

0.2 μm polycarbonate filter, cut into pieces and used as template for DNA isolation with the innuPREP Bacteria DNA Kit (Analytik Jena AG) following the manual. The yield was of 200 μL with $\sim 1\mu\text{g } \mu\text{L}^{-1}$ DNA, quantified by spectrophotometric quantification with NanoDrop.

2.5.2 DNA sequencing

DNA sequencing was performed by BaseClear B.V. (Leiden, The Netherlands) using the Illumina HiSeq2500 system.

2.5.3 Genome assembly and annotation

Genome assembly and annotation was performed by Dr. Thomas Schott. Paired Illumina reads were assembled using SPAdes (Nurk et al., 2013) v 3.10.1 (k-mers 57, 65, 77, 85, 89, 95, 101, 105, 109). In addition, a subset of 875000 randomly selected read pairs was assembled using mira (Chevreux et al., 1999) v4.9.4 with default settings. Contigs resulting from both assemblies with a minimum average coverage of 40x and a minimum length of 500 nucleotides were manually merged using Gap5 (Bonfield & Whitwham, 2010) of the Staden package. The final contigs were uploaded to The RAST Server (Aziz et al., 2008) for automated annotation.

2.6 Analysis of cell counts

2.6.1 DAPI stained epifluorescence microscopy

Sample fixation was done with glutaraldehyde (2.5% final concentration) for 1 h at room temperature. Fixed samples containing Mn particles were diluted with at least 5 times the sample volume of a hydroxylamine solution (1.5 M $\text{NH}_2\text{OH} \cdot \text{HCl}$ dissolved in 0.25 M HCl) and treated for 5 minutes in an ultrasonic bath before the samples were filtered onto 0.2 μm polycarbonate filters. Fixed samples without metal particles were treated the same way, but phosphate buffered saline (1x PBS) instead of hydroxylamine was used for dilution. Filters were washed with 0.2 μm filtered MilliQ water, dried in the dark and embedded in DAPI contain-

ing fluorescence oil (1.1 mL Citifluor, 0.2 mL Vecta-shield, 0.1 mL 1x PBS including 1.4 µg DAPI). Cell counts were enumerated at 1000x magnification.

2.6.2 Flow-cytometry

Staining for flow-cytometry was done with nucleic acid stain SYBR Green I (Molecular Probes) following the technique of Marie et al. (1997). A subsample of a Mn containing glutaraldehyde fixed sample was diluted in tenfold the volume of a hydroxylamine solution and treated for 5 minutes in an ultrasonic bath. Subsequently, half the volume of the hydroxylamine solution of a 2.3 M 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES - in MilliQ water) buffer solution was added to raise the pH to neutral condition. Samples without Mn were treated in the same way, but 1x PBS instead of hydroxylamine and HEPES was used instead. A subsample of this solution was filled up to 400 µl with sterile filtered MilliQ water and 50 µl sterile (0.2 µm) filtered staining solution (Tab. 7) together with 10 µl bead solution (1:2 x 10¹⁰ dilution in sterile filtered MilliQ water of 0.86 µm FL3 beads, Duke Scientific Corp., Cat. No. R900) were added. Chemical blanks of MilliQ water, PBS and hydroxylamine with HEPES were treated as described for the samples. Final samples were incubated in the dark at room temperature for at least 30 minutes. Samples were analyzed using FACSCalibur (Beckton Dickinson) in medium flow rate and excitation wavelength of 488 nm (blue) with a 15 mW air cooled argon-ion laser. Forward scatter (FSC – 488/10 nm), side scatter (SSC – 488/10 nm), FL1 (530/30 nm) and FL3 (>670 nm) were recorded. Within the run time of 188 s per sample, 105 µL were analyzed according to flow rate measurements. To account for fluctuating flow rates, a daily mean bead count was calcu-

Table 7: Components of the SYBR Green I staining solution.

Solution	Volume	Final concentration
Potassium citrate	1200 µL	2.4 M
Dimethyl sulfoxide (DMSO)	245 µL	0.2 M
SYBR Green I (10000x)	5 µL	-

lated from all measurements at the respective day and was used to correct the bacterial cell count according to Eq. 2.2.

$$\text{corrected cell counts} = \text{cell counts} * \frac{\text{mean bead count at respective day}}{\text{bead count in respective sample}} \quad 2.2$$

Data analysis was done with Flowing Software version 2.5.1 (Perttu Terho, Turku Centre for Biotechnology, Finland; www.flowingsoftware.com). Gates for cells and beads were chosen on the basis of dot plots of FL3 against FL1 on logarithmic scales. Cell counts were calculated with Eq. 2.3.

$$\text{Cells counts mL}^{-1} = \frac{\text{Events}_{\text{cells}} - \text{Events}_{\text{blank}}}{V_{\text{analyzed}}} * \text{DF}_{\text{fix}} * \text{DF}_{\text{proc}} * \text{DF}_{\text{cyt}} \quad 2.3$$

With $\text{Events}_{\text{cells}}$ = event counts within cell gate, $\text{Events}_{\text{blank}}$ = event counts within the cell gate in blank, V_{analyzed} = analyzed sample volume in mL, DF_{fix} = dilution factor due to sample fixation, DF_{proc} = dilution factor due to sample processing and DF_{cyt} = dilution factor due to preparation for flow cytometry.

Dilution factors (DF) were calculated according to Eq. 2.4, 2.5 and 2.6.

$$\text{DF}_{\text{fix}} = \frac{V_{\text{fix}} + V_{\text{sample}}}{V_{\text{sample}}} \quad 2.4$$

$$\text{DF}_{\text{proc}} = \frac{V_{\text{acid/PBS}} + V_{\text{fix.sample}} + V_{\text{HEPES/PBS}}}{V_{\text{fix.sample}}} \quad 2.5$$

$$\text{DF}_{\text{cyt}} = \frac{V_{\text{proc.sample}} + V_{\text{MQ}} + V_{\text{beads}} + V_{\text{SYBR}}}{V_{\text{prep.sample}}} \quad 2.6$$

With V_{fix} = volume fixative added, V_{sample} = volume sample added, $V_{\text{acid/PBS}}$ = volume of hydroxylamine solution or 1x PBS added, $V_{\text{fix.sample}}$ = volume of fixed sample added, $V_{\text{HEPES/PBS}}$ = volume of buffer or 1x PBS added, $V_{\text{proc.sample}}$ = volume of sample added processed with hydroxylamine and HEPES or 1x PBS, V_{MQ} = volume MilliQ water added, V_{beads} = volume bead solution added and V_{SYBR} = volume SYBR Green I staining solution added.

2.7 Chemical analyses

2.7.1 Sulfur species

Sulfate (SO_4^{2-})

Sulfate was quantified by precipitation as BaSO_4 and photometry against a standard series. A 1 mL sterile filtered subsample was added to 1 mL BaCl_2 solution for BaSO_4 precipitation. The BaCl_2 solution was a mixture of two components. Component 1 was a mixture of MilliQ water and glycerine with a ratio of 2:3 (vol.%), respectively. Component 2 was 40.95 mM BaCl_2 solution in MilliQ water. Components 1 and 2 were mixed with a ratio of 3:2 (vol.%), respectively. Samples were stored at 4 °C. Samples were shaken thoroughly and treated with ultrasonic prior to turbidity measurement against a calibration series using the TECAN infinite M200 PRO plate reader with photometric measurement at 436 nm wavelength. The samples were shaken for 10 minutes prior to the beginning of the measurements and additionally 10 seconds before each measurement.

Thiosulfate ($\text{S}_2\text{O}_3^{2-}$) and sulfite (SO_3^{2-})

Thiosulfate and sulfite were analyzed by derivatization with monobromobimane against a standard series. A 0.5 mL 0.2 μm filtered subsample was added to 25 μL of HEPES/EDTA buffer (200 mM/50 mM in MilliQ, respectively) and 25 μL of a monobromobimane solution (48 mM in acetonitrile). The mixture was kept in the dark at room temperature for 30 minutes for derivatization. Derivatization was stopped by the addition of 25 μL methanesulfonic acid (324 mM in MilliQ water). Samples were diluted with MilliQ water and measured daily. Samples and calibration series were analyzed using BioTek high pressure liquid chromatography (HPLC) system with pump 525 (1 mL min^{-1}), oven 582 (40 °C), column LiChrospher 60 RP-Select B (5 μm) 125x4 and a Jasco FP 1520 detector (excitation at 380 nm, emission at 480 nm). Data were analyzed with the program Geminix III Version 1.10.3.7. Eluent A: 0.25% acetic acid; Eluent B: 100% methanol. Gradient protocol: 0 min 100% A, 2 min 100% A, 5.5

min 92% A, 8 min 68% A, 12 min 68% A, 13 min 0% A, 18 min 0% A, 19 min 100% A, 23 min 100% A. With these adjustments, the $\text{S}_2\text{O}_3^{2-}$ peak appeared after 10 minutes and the SO_3^{2-} peak after 8 minutes.

Elemental sulfur (S^0)

Samples were immediately fixed by adding zinc acetate (0.5% w/v final concentration) to precipitate H_2S as ZnS to avoid chemical oxidation to S^0 . Chloroform was added and intensively mixed for several minutes to dissolve S^0 in the chloroform phase. The chloroform phase at the bottom was transferred into a new tube and stored at $-80\text{ }^\circ\text{C}$ until HPLC measurements. 100 μL of the chloroform extract were diluted with 400 μL methanol and measured with HPLC against a standard series. S^0 was analyzed using BioTek HPLC System with pump 525 (1 mL min^{-1}), oven 582 (25 $^\circ\text{C}$), column LiChrospher 100 RP-18 B (5 μm) 125x4 and DAD 545V detector (wavelength 265 nm and 6nm bandwidth). Data analysis was done with the program Geminyx III Version 1.10.3.7. An isocratic gradient with 100% methanol was applied. With these adjustments, the S^0 peak appeared after 4.4 min.

Hydrogen sulfide (H_2S)

Total H_2S was determined photometrically with the Cline method (Cline, 1969) against a standard series at a wavelength of 670 nm.

2.7.2 Metals and calcium (Ca)

After distinct sample preparation (see below) dissolved and particulate concentrations of Fe, Mn, S and Ca were determined by inductively coupled plasma optical emission spectrometry (ICP-OES - iCAP 7400 Duo, Thermo Fisher Scientific) using an external calibration ranging from 0.18 – 146 μM for Mn and from 0.012 – 2 mM for Ca. The Mn wavelength 260.6 nm and the Ca wavelength 318.1 nm were used in radial mode. Sc (316.4 nm) was used as internal standard to compensate matrix effects and instrument fluctuations. If necessary, samples were diluted with 2 vol.% HNO_3 to fit within the calibration ranges of Mn and Ca. Precision

and accuracy were checked by using acid digestions of the international reference material green river shale (SGR-1b) from U.S. Geological Survey (USGS) and were below 2%.

Total dissolved Fe, Mn, S and Ca

0.5 mL of a 0.2 μm filtered subsamples were filled in preconditioned (filled and stored with 2% HNO_3) microcentrifuge tubes, acidified with 10 μL 65% HNO_3 and stored at 4 $^\circ\text{C}$.

Dissolved reactive Mn (Mn_{react})

Dissolved reactive Mn was analyzed according to the protocol of Schnetger and Dellwig (2012). Leftovers of 0.2 μm filtrated subsamples were stored in sterile microcentrifuge tubes at oxic conditions for 48h at room temperature and filtered again with 0.2 μm . Total dissolved Mn of the filtrate was quantified as described above. Dissolved reactive Mn was calculated with Eq. 2.7.

$$\text{Diss. reactive Mn} = \text{total diss. Mn at sampling time} - \text{total diss. Mn after 48h} \quad 2.7$$

Particulate Fe, Mn, S and Ca

Unfiltered subsamples were centrifuged in a Beckman Coulter X15R System with a SX4750 rotor at 3200 rpm for 15 min at 10 $^\circ\text{C}$. The supernatant was discarded and the pellet was dispersed in MilliQ water, shaken and centrifuged as described above. This washing step was done twice. After the second washing step, the supernatant was discarded and the residue was dried at 60 $^\circ\text{C}$ and stored at room temperature. The pellet was dissolved with a hydroxylamine solution (1.5 M $\text{NH}_2\text{OH} \cdot \text{HCl}$ dissolved in 0.25 M HCl) and analyzed as described above.

Calculation of reduced Mn in the particulate Mn phase

During precipitation of reduced Mn(II) as $\text{Mn}(\text{Ca})\text{CO}_3$, the particulate Mn phase comprised new reduced and previously present oxidized Mn. Because precipitated rhombohedral shaped $\text{Mn}(\text{Ca})\text{CO}_3$ contains exclusively reduced Mn, the amount of reduced Mn in the particulate phase can be quantified with Eq. 2.8.

$$\text{Mn}_{part.(red)} = \text{Mn}_{part.} * \frac{\left(\frac{\text{Ca}}{\text{Mn}}\right)_{total}}{\left(\frac{\text{Ca}}{\text{Mn}}\right)_{rhomb}} \quad 2.8$$

Total particulate Ca to Mn ratio was analyzed with ICP-OES as described above. Starting Ca content of the respective experiment was subtracted and treated as a blank value. About 20-30 rhombohedral $\text{Mn}(\text{Ca})\text{CO}_3$ precipitates of the respective sample were analyzed by SEM-EDX punctual measurements to determine the molar ratio of single $\text{Mn}(\text{Ca})\text{CO}_3$ precipitates (see chapter 2.9.1).

2.7.3 Total inorganic carbon (TIC)

Direct TIC analysis was applied on dried material with a multi-EA 4000 (Analytic Jena). Samples were treated with 40% H_3PO_4 and the released CO_2 was analyzed by an infrared detector. Pure standard CaCO_3 (12.0% TIC) was used for calibration.

2.7.4 Cellular polyphosphate (polyP)

Glutaraldehyde fixed cells of *S. marisnigri* were enriched by centrifugation in a Beckman Coulter X15R System with a SX4750 rotor at 3200 rpm for 15 min at 10 °C. The supernatant was discarded. Particulate Mn was removed by dissolution in three consecutive series of hydroxylamine addition (see chapter 2.6), centrifugation and discarding of the supernatant. The Mn-particle free cell pellet was rinsed with PBS, centrifuged and the supernatant was discarded. Polyphosphate staining with tetracyclin was performed following the protocol of Koch et al. (2013). Cells were identified by forward and sideward scatter and separated by either positive (polyP+) or negative (polyP-) staining with tetracyclin by fluorescence activated cell sorting (FACS) with FACSARIA III (Becton Dickinson, Heidelberg, Germany). In a subsample, the cell concentration of the sorted cell solutions was enumerated by flow cytometry. The P content of the sorted samples was analyzed by quadrupol ICP-MS (iCAP Q, Thermo Fisher Scientific) in KED mode. The collision cell was filled with He with 8% H_2 to eliminate putative interference of $^{15}\text{N}^{16}\text{O}$. ^{62}Ni was detected next to ^{31}P to account for signal

interferences due to double ionized $^{62}\text{Ni}^{++}$. System calibration was performed with an ICP P standard (Alfa Aesar) from 1 to 100 ppb. The amount of P accumulated as polyP by *S. marisnigri* was calculated by subtracting the mean cellular P content of polyP- cells from polyP+ cells.

2.7.5 Nitrate (NO_3^-) and nitrite (NO_2^-)

NO_3^- and NO_2^- were analyzed following the protocol of García-Robledo et al. (2014) with a little modification. NO_3^- reduction with vanadium chloride was performed overnight without heating in a cooling bath.

2.8 Analysis of O_2 , pH and H_2S with microsensors

Equipment used for micosensor analysis was purchased from Unisense (Denmark). Calibration and analysis were performed according to the manual and recorded with the software SensorTrace Logger provided by the manufacturer.

2.9 Combined imaging and elemental quantification

2.9.1 Scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX) analysis

Imaging and element analysis were performed with a Merlin Compact SEM (variable pressure, in-lens SE and HE-SE2 detectors) from Zeiss and elemental semi-quantification with an equipped EDX (Oxford Instruments).

SEM imaging

Samples were prepared on 0.2 μm polycarbonate filters and sputter coated with a 10 nm chromium layer for imaging of bacterial cells. Imaging was done with the HE-SE2 detector, aperture adjusted between 10 and 30 μm and 3 kV electron beam intensity. For high quality images, 2048 x 1536 px were recorded with line averaging of 8.

EDX analysis

Samples were prepared on 0.2 μm polycarbonate filters and sputter coated with a 10 nm elemental carbon layer for element analysis with EDX. Element analysis was performed with the HE-SE2 detector, 15 kV beam current and 60 μm aperture. EDX data were recorded in mass% and was transformed to molar ratios by dividing the value with the respective atomic weight. C was excluded from analysis.

Automated particle analysis

Samples for automated particle analysis shown in this work were prepared as described for NanoSIMS analysis. Automated particle analysis was performed with the program Inca (V. 5.05, Oxford Instruments). Particle identification was done at 1000x magnification and 2048 x 1526 px resolution by contrast and grey values, which were adjusted to 110 – 255. Particles smaller than 0.1121 μm ($\text{ECD } 1.79 \mu\text{m}^2 \triangleq 800 \text{ px}$) were excluded from analysis. 1000 particles per sample were analyzed within fields of 1000 μm^2 at an electron beam intensity of 10 kV and a pixel dwell time of 10 μs . A particle threshold of 25 per field was chosen. With this adjustments, a minimum of 40 fields at different filter locations were analyzed. Each particle was analyzed in full area with two runs, the first with 3 s and the second with 5 s and a process time of 5 s. Co was used for drift compensation. Au was excluded for analysis data were exported as mass% and transformed as described before.

2.9.2 Nanoscale secondary ion mass spectrometry (NanoSIMS)

Samples for NanoSIMS analysis were prepared on 0.2 μm polycarbonate filter material. Dried filters were sputter coated with a 30 nm gold layer for electrical conductivity. SIMS imaging was performed by Dr. Angela Vogts using a NanoSIMS 50 L from Cameca (Gennevilliers, France). Samples were implemented for 200 s with a $^{133}\text{Cs}^+$ ion beam at a beam current of 600 pA. Secondary ions were detected using mass detectors equipped with electron multipliers (Hamamatsu, Hamamatsu City, Japan). For analysis, the secondary ions $^{16}\text{O}^-$, $^{12}\text{C}^{14}\text{N}^-$, $^{31}\text{P}^-$,

Table 8: Area analyzed with Nano-SIMS at the respective sample days shown in Fig. 14.

Day	Ion source	Raster μm
0	Cs^+	47 x 47
	O^{2+}	36 x 36
3	Cs^+	45 x 45
	O^{2+}	36 x 36
6	Cs^+	48 x 48
	O^{2+}	36 x 36
13	Cs^+	48 x 48
	O^{2+}	36 x 36
17	Cs^+	47 x 47
	O^{2+}	35 x 35

$^{32}\text{S}^-$ and $^{55}\text{Mn}^{16}\text{O}^-$ were generated with a $^{133}\text{Cs}^+$ ion beam and the secondary ions $^{39}\text{K}^+$ and $^{40}\text{Ca}^+$ were generated with an O^{2+} ion beam at a beam current of 1 pA and a pixel dwell time of $125 \mu\text{s px}^{-1}$, each. SIMS analysis was done with a resolution $1024 \times 1024 \text{ px}$ in varying sample areas (Tab. 8). 30 planes were recorded for each analysis. Data were evaluated with Look@NanoSIMS software (Polerecky et al., 2012). Recorded planes were drift-corrected and accumulated. To assemble SIMS analyses

from both ion sources, images from $^{16}\text{O}^{2+}$ were aligned on $^{133}\text{Cs}^+$ images. Thereby, overlays are cropped to the lower size of the $^{16}\text{O}^{2+}$ derived images.

2.9.3 He- ion microscopy and secondary ion mass spectrometry (HIM-SIMS)

Glutaraldehyde fixed samples for HIM-SIMS analysis were prepared on $0.2 \mu\text{m}$ polycarbonate filters rinsed with MilliQ water and analyzed by Jelena Lovric at Luxembourg Institute of Science and Technology (LIST), Advanced Instrumentation for Ion Nano-Analytics (AINA), Materials Research and Technology Department 41, rue du Brill, L-4422 Belvaux. Analytical information and secondary electron images were obtained with a Secondary Ion Mass Spectrometry (SIMS) system specifically developed at LIST for Zeiss ORION NanoFab Helium Ion Microscope (HIM) (Wirtz et al., 2015; Dowsett et al., 2017). The secondary electron images were acquired with a helium ion beam at a beam energy of 20 keV in a matrix of 2048×2048 pixels with a dwell time of $20 \mu\text{s px}^{-1}$ and line averaging (8 lines). The field of view was $16 \times 16 \mu\text{m}$ and ion dose was $7.73 \times 10^{15} \text{ ions cm}^{-2}$. The spectrometer was tuned for the simultaneous detection of the $^{40}\text{Ca}^+$, and $^{55}\text{Mn}^+$ signals in the positive polarity. The $^{16}\text{O}^-$ and $^{12}\text{C}^{14}\text{N}^-$ ion cluster signals have been detected in negative polarity. Secondary ion images were acquired with a neon beam at 20 keV in a matrix of

512 × 512 pixels and a beam dwell time of 3 ms px⁻¹. In positive polarity, the field of view was 15 × 15 μm and ion dose was 1.42 × 10¹⁹ ions cm⁻². In negative polarity, the field of view was 14 × 14 μm and ion dose was 1.63 × 10¹⁹ ions cm⁻². Laplacian pyramid image fusion of the secondary electron micrograph and secondary ion images of Mn⁺ and CN⁻ was performed after (Vollnhals et al., 2017).

2.10 Rate calculations with exponential curve fitting

The chemical reaction of MnO₂ and H₂S (Tab. 2) was forced from a reaction of second order type to a pseudo-first order type by adding large amounts of MnO₂ (10-20 mM) and single small additions of H₂S (20-40 μM) as it is done in chemical studies (e.g. Yao & Millero (1993)). The concentration decrease of H₂S against time was used to calculate H₂S oxidation rates by fitting Eq. 2.9 to concentrations of H₂S with the nonlinear least square fit (nls) function in R by adjusting k and a.

$$\frac{C_{H_2S(t)}}{C_{H_2S(0)}} = e^{(a+kt)} \quad 2.9$$

With $C_{H_2S(t)}$ = H₂S concentration at time t, $C_{H_2S(0)}$ = H₂S concentration added initially, k the reaction rate coefficient, t the time in minutes and a the variable to adjust for the y-intercept. The reaction rate coefficient k (min⁻¹) can be multiplied with the concentration of H₂S to receive H₂S oxidation rates.

2.11 Numerical modeling

With a numerical model the influence of bacterial H₂S oxidation at the lower border of the Black Sea suboxic zone onto the depth related concentration profile of H₂S was visualized. In the modeling approach from Schulz (2006) the differential equation for diffusive transport (Fick's second law – Eq. 2.10),

$$\frac{\Delta c}{\Delta t} = D \cdot \frac{\Delta^2 c}{\Delta x^2} \quad 2.10$$

with D = diffusion coefficient, c = concentration, t = time and x = distance coordinate is solved by using the explicit numerical solution which was adapted from Schulz-Vogt et al. (2019) shown in Eq. 2.11.

$$C_{H_2S}(x,t+\Delta t) = C_{H_2S}(x,t) + \Delta t \cdot D_x \cdot \frac{C_{H_2S}(x+\Delta x,t) - 2 \cdot C_{H_2S}(x,t) + C_{H_2S}(x-\Delta x,t)}{\Delta x^2} + \Delta t \cdot k_{bio(A \text{ or } P)} \cdot C_{H_2S}(x,t) \cdot Epsilon_{bact.}(x) \quad 2.11$$

With C_{H_2S} = concentration of H_2S at a given depth x and time t , D_x = diapycnical diffusivity constant at the depth x as determined by (Gregg & Yakushev, 2005), $k_{bio(A \text{ or } P)}$ = cell specific H_2S oxidation rate as determined described in chapter 2.10 and $Epsilon_{bact.}$ = cellular abundance of *Epsilonbacteraeota* at the respective depth x .

Figure 7: Screenshot of the numerical model used for the calculation of H_2S profiles with different oxidation rates. Modeling results with the value $k_{bio(A)} = -3.16 \times 10^{-14} \text{ L cell}^{-1} \text{ s}^{-1}$ after 3 years of model run in steady state are shown.

As starting condition, 10 μM H_2S are implemented in 120 m depth which represents in situ concentrations (Fig. 2A). In each calculation interval of $\Delta t = 8000$ s, the concentration of H_2S is calculated in the depth range from 80 to 120 m with an integrated depth for each cell of $\Delta x = 0.25$ m. The calculated H_2S concentrations after a calculation interval are the basis for the next calculation. Different oxidation rates per cell for *Epsilonbacteraeota* are implemented and steady state conditions were displayed. If no steady state was achieved after 3 years of modeling, the concentration profile after 3 years were displayed (Fig. 7).

2.12 Experimental design, cultivation conditions and specific supplementation

In the present work, experimental conditions were adjusted based on the respective question. If not mentioned otherwise, medium was prepared as described in 2.1. Experimental design and growth conditions are listed as they appear in the results section. To avoid any misunderstandings, the following details should be read along with the respective passage in the results part.

2.12.1 Particle dynamics analyzed with NanoSIMS

For NanoSIMS analysis focusing on the dynamics of Mn particles, *S. marisnigri* was cultivated with the additions listed in Tab. 9.

2.12.2 Dynamic of Mn and S species during growth of *S. marisnigri*

S. marisnigri cultivated with MnO_2 and $\text{S}_2\text{O}_3^{2-}$

S. marisnigri was cultivated in triplicates with one sterile control in 500 mL medium with MnO_2 as electron acceptor and $\text{S}_2\text{O}_3^{2-}$ as electron donor. Sampling was performed by ex-

Table 9: Concentration of added electron acceptors and donors and basic information for growth of *S. marisnigri* for the Nano-SIMS time series shown in Fig. 14.

e^- acceptor	$\text{C}_{\text{e- acceptor}}$	e^- donor	$\text{C}_{\text{e- donor}}$	Volume	Cell counting
MnO_2	6.7 mM	$\text{S}_2\text{O}_3^{2-}$	1.7 mM	150 mL	Microscopy

Bottles were connected with gas tight iso-versinic tubing and autoclaved. 10 mL 1 M MnO_2 solution were added to bottle A and C, and 5 ml 1 M Na_2S stock solution were added to bottle B (Fig. 9). H_2S was added continuously with a peristaltic pump (ISMATEC, IPC-N) from bottle B to bottle A and C with a pump speed of $3 \mu\text{L min}^{-1}$. The experiment was running for two days before cells were added (day 0). Pump speed was increased to $7.5 \mu\text{L min}^{-1}$ at day 12. All bottles were constantly stirred. Sampling for SO_4^{2-} , S^0 , diss. reactive Mn, diss. Mn, part. Mn and cell numbers was performed as described earlier.

2.12.3 *S. marisnigri* and *S. baltica* grown with NO_3^- and H_2S additions

S. marisnigri and *S. baltica* together with sterile controls were cultivated with 6.7 mM NO_3^- as electron acceptor in serum bottles with 150 mL medium. Small additions of 100 μL , 200 μL or 300 μL out of a 10.79 mM Na_2S stock solution resulting in 7.2 μM , 14.4 μM or 21.6 μM , respectively, were made several times per day. Samples for cell numbers and sulfide were taken every second day. Cell numbers were enumerated with epifluorescence microscopy.

2.12.4 *S. marisnigri* grown with MnO_2 and additions of H_2S or H_2S pre-reacted with MnO_2

Two parallels with triplicates each were prepared in serum bottles containing 150 mL medium, 6.7 mM MnO_2 and *S. marisnigri*. Small additions of 100 μL , 200 μL or 300 μL out of either stock solution 1 (H_2S) or 2 ($\text{Mn}/\text{H}_2\text{S}$) were added several times per day. Stock solution 1 was prepared by adding 1.5 mL 1 M Na_2S stock solution to ~150 mL anoxic and sterile medium. Stock solution 2 was prepared by adding 3 mL 1 M MnO_2 , 1.5 mL 1 M Na_2S

Table 10: S-composition of stock solution 1 (H_2S) and 2 ($\text{Mn}/\text{H}_2\text{S}$). n.d. = not detectable; n.q. = not quantifiable.

Stock solution	H_2S	S^0	$\text{S}_2\text{O}_3^{2-}$	SO_4^{2-}	Sum
H_2S	10.8 mM	n.q.	n.d.	0.1 mM	10.9 mM
$\text{Mn}/\text{H}_2\text{S}$	n.d.	9.17 mM	0.34 mM	<0.01 mM	9.5 mM

and 0.3 mL 30% HCl to ~150 mL anoxic and sterile medium. HCl was added in 3 steps of 100 μ L to keep the pH at 7.5, which rose by the chemical reaction of H₂S and MnO₂. Sulfur composition of stock solution 1 (H₂S) and 2 (Mn/H₂S) are depicted in Tab. 10.

2.12.5 Determination of H₂S oxidation rates of *S. marisnigri*

Six glass bottles were filled with 500 mL medium and 10 mL 1 M MnO₂ were added. To three bottles 5 mL 200 mM Na₂S₂O₃ and *S. marisnigri* were added (Culture parallels); the others remained unchanged (control). The addition of S₂O₃²⁻ to control bottles had to be omitted. Preliminary tests showed a pH dependent H₂S oxidation activity, which stopped at approximately pH 8, which is consistent with the chemical oxidation of H₂S with S₂O₃²⁻ according to the work of Siu & Jia (1999). In culture parallels, S₂O₃²⁻ was completely consumed after 12 days of growth, which was measured prior to the additions of H₂S. Bottles were opened, placed in a 10 °C water bath and a pH and H₂S microsensor were placed in the medium as shown in Fig. 10. The medium was constantly stirred and the headspace was flushed with a low Ar stream during the time of the experiment to avoid O₂ contaminations. Bottles were treated with sodium azide (20 mM final concentration, 1h incubation) or heat (pasteurization, 80 °C for 1 h) after 8 (culture) or 5 (sterile control) additions of H₂S. Then another 3 additions of H₂S were made. Data were analyzed as described in 2.10.

Figure 10: Setup for the determination of H₂S oxidation rates with a pH and a H₂S microsensor.

2.12.6 Dissimilatory metabolism – electron acceptors

As potential electron acceptors for the oxidation of $\text{S}_2\text{O}_3^{2-}$, O_2 , NO_3^- , nitrite (NO_2^-) and a variety of metal oxides were tested. Additionally, the ability for SO_4^{2-} - reduction, disproportionation of $\text{S}_2\text{O}_3^{2-}$ and S^0 and fermentation of organic C was investigated.

O_2

Bottles were prepared as described in 2.12.12 – oxygen tolerance, but no electron acceptor was added.

NO_3^-

Medium was supplemented as listed in Tab. 11. In a second experiment, *S. marisnigri*, pre-grown with NO_3^- as electron acceptor, was cultivated in triplicates in 500 mL medium containing 4 mM NaNO_3 and 3.5 mM $\text{Na}_2\text{S}_2\text{O}_3$. After 22 days of growth, MnO_2 was added to a final concentration of 3.5 mM. Cell numbers were enumerated with epifluorescence microscopy.

NO_2^-

Medium was supplemented as listed in Tab. 12.

Metal oxides

To ~150 mL medium containing 2.7 mM $\text{Na}_2\text{S}_2\text{O}_3$, 670 μM Fe_2O_3 or FeCl_3 were added twice a week, because (Labrenz et al., 2013) suggested potentially toxic effects of high iron concentrations. Ability of *S. gotlandica* to reduce MnO_2 was performed with 2.7 mM $\text{Na}_2\text{S}_2\text{O}_3$ and

Table 11: Concentration of added electron acceptors and donors and basic information to test for NO_3^- reduction.

e- acceptor	C _e - acceptor	Volume	e- donor	C _e - donor	Cell counting	Transfers
NO_3^-	10 mM	100 mL	$\text{S}_2\text{O}_3^{2-}$	10 mM	Flow cytometry	2

Table 12: Concentration of added electron acceptors and donors and basic information to test for NO_2^- reduction.

e- acceptor	C _e - acceptor	Volume	e- donor	C _e - donor	Cell counting	Transfers
NO_2^-	5 mM	100 mL	$\text{S}_2\text{O}_3^{2-}$	10 mM	Flow cytometry	2

6.7 mM MnO_2 as it is applied by default for *S. marisnigri* and *S. baltica*. As control experiments, two bottles were prepared as described in 2.1, but 1.7 μM resazurin as redox indicator were added. One bottle was treated with 3.8 mM cystein 7 days before inoculation to eliminate putative O_2 contaminations, the other remained unchanged. Both were inoculated with cells and 2.7 mM $\text{Na}_2\text{S}_2\text{O}_3$. Cells were enumerated with epifluorescence microscopy. Amorphous FeOOH and goethite were added as electron acceptor in batch type cultivation with concentrations below 10 mM together with 5 mM $\text{Na}_2\text{S}_2\text{O}_3$.

2.12.7 Dissimilatory metabolism – electron donors

As potential electron donors (e^- - donors) for the reduction of either MnO_2 or NO_3^- , elemental sulfur (S^0), sulfite (SO_3^{2-}), hydrogen (H_2) and organic carbon (C- org.) were tested. Experimental conditions are summarized in Tab. 13.

S^0

Stock solution of colloidal S^0 was prepared anoxic and non-sterile as described in 2.2.2.

SO_3^{2-}

In the third transfer of *S. gotlandica*, 10 mM instead of 5 mM Na_2SO_3 were added as electron donor.

H_2

Growth with H_2 as electron donor or in the presence of H_2 was done with a negative (no H_2 , no $\text{Na}_2\text{S}_2\text{O}_3$) and a positive control (H_2 and $\text{Na}_2\text{S}_2\text{O}_3$). H_2 was applied by flushing the headspace (~ 20 ml) with 0.2 μm filtered H_2 gas for 30 s generated with a H_2 generator (Horiba STEC 3200C).

Organic carbon (C- org.)

Organic carbon was added as an equal mix of acetate ($\text{C}_2\text{H}_4\text{O}_2$), propionate ($\text{C}_3\text{H}_6\text{O}_3$) and succinate ($\text{C}_4\text{H}_6\text{O}_4$). Two transfers were made with *S. marisnigri* and three transfers were made with *S. baltica* and *S. gotlandica*.

Table 13: Concentration of added electron acceptors and donors and basic information to test for potential electron donors.

e ⁻ donor	C _{e-} donor	Volume	e ⁻ acceptor	C _{e-} acceptor	Cell counting	Transfers
S ⁰	~4 mM	100 mL	MnO ₂ /NO ₃ ⁻	5 mM	Flow cytometry	2
Na ₂ SO ₃	5 (10) mM	100 mL	MnO ₂ /NO ₃ ⁻	5 mM	Flow cytometry	2 (3)
H ₂	H ₂ gas	150 mL	MnO ₂ /NO ₃ ⁻	6.7 mM	Microscopy	1
C- org. mix	7.5 mM	100 mL	MnO ₂ /NO ₃ ⁻	5 mM	Flow cytometry	2 (3)

2.12.8 Disproportionation of S⁰ and S₂O₃²⁻

Disproportionation was tested by adding solely S₂O₃²⁻ or S⁰ as energy source to cultivation medium with bacteria as listed in Tab. 14.

2.12.9 SO₄²⁻ - reduction

Organic carbon was added as an equal mix of acetate (C₂H₄O₂), propionate (C₃H₆O₃) and succinate (C₄H₆O₄) as listed in Tab. 15.

2.12.10 Fermentation

Organic carbon was added as an equal mix of acetate (C₂H₄O₂), propionate (C₃H₆O₃) and succinate (C₄H₆O₄) shown in Tab. 16.

Table 14: Concentration of added electron acceptors and donors and basic information to test S⁰ and S₂O₃²⁻ disproportionation.

S- component	C _S -component	Volume	Cell counting	Transfers
S ⁰	4 mM	100 mL	Flow cytometry	3

C- component	C _C -component	Volume	Cell counting	Transfers
C-org. mix	7.5 mM	100 mL	Flow cytometry	1(2)

2.12.11 Assimilatory metabolism

The potential of the three *Sulfurimonas* species to fix molecular nitrogen (N_2) and to grow with organic carbon (C- org.) as carbon source was investigated.

N_2 – fixation

Medium was prepared without NH_4Cl as N-source. NO_3^- was omitted as electron acceptor for *S. gotlandica*, instead, O_2 was provided by flushing the ~ 15 mL headspace with sterile filtered breathing air (Tab. 17).

Organic carbon (C- org.)

Medium was prepared with HEPES as pH buffer and Ar gas instead of N_2 with 20% CO_2 was used for de-oxygenation. The pH was adjusted to 7.5 with NaOH and HCl. Acetate ($C_2H_4O_2$), propionate ($C_3H_6O_3$) or succinate ($C_4H_6O_4$) was added prior to inoculation in concentrations specified in Tab 18.

2.12.12 Abiotic factors influencing growth

Added components to cultivation medium to test for abiotic growth factors are listed in Tab. 19.

Table 17: Concentration of added electron acceptors and donors and basic information to test for N_2 -fixation. Two transfers were made for *S. gotlandica* and *S. marinsigri* and three transfers were made for *S. baltica*.

Experiment	Volume	e- acceptor	C _{e-} acceptor	e- donor	C _{e-} donor	Cell counting	Transfers
N_2 – fixation	100 mL	MnO_2/O_2	10 mM/gas	$S_2O_3^{2-}$	5 mM	Flow cytometry	2(3)

Table 18: Concentration of added electron acceptors and donors and basic information to test for heterotrophic growth on a variety of organic carbon sources. 4 mM $S_2O_3^{2-}$ was added for *S. marinsigri* and *S. gotlandica*. 5 mM $S_2O_3^{2-}$ was added for *S. baltica*.

C- source	C _{C-source}	Volume	e- acceptor	C _{e-} acceptor	e- donor	C _{e-} donor	Cell counting
HCO_3^- (pos. C.)	10 mM	100 mL	MnO_2/NO_3^-	10 mM	$S_2O_3^{2-}$	4(5) mM	Microscopy

Acetate	15 mM	100 mL	MnO_2/NO_3^-	10 mM	$S_2O_3^{2-}$	4(5) mM	Microscopy
Propionat	15 mM	100 mL	MnO_2/NO_3^-	10 mM	$S_2O_3^{2-}$	4(5) mM	Microscopy
Succinate	15 mM	100 mL	MnO_2/NO_3^-	10 mM	$S_2O_3^{2-}$	4(5) mM	Microscopy

Table 19: Concentration of added electron acceptors and donors and basic information to test for abiotic factors influencing growth of the three *Sulfurimonas* species.

Experiment	Volume	e- acceptor	C _{e-} acceptor	e- donor	C _{e-} donor	Cell counting
Temperature	100 mL	MnO ₂ /NO ₃ ⁻	10 mM	S ₂ O ₃ ²⁻	5 mM	Microscopy
Salinity	100 mL	MnO ₂ /NO ₃ ⁻	10 mM	S ₂ O ₃ ²⁻	5 mM	Flow cytometry
pH	100 mL	MnO ₂ /NO ₃ ⁻	10 mM	S ₂ O ₃ ²⁻	5 mM	Flow cytometry
O ₂ tolerance	50 mL	MnO ₂ /NO ₃ ⁻	10 mM	S ₂ O ₃ ²⁻	5 mM	Flow cytometry

Temperature

Bottles were placed in dark, temperature controlled rooms or climate cabinets. Bottles at 0 °C were placed in an isolated box filled with ice and water in a 4 °C climate controlled room. Ice was refilled frequently. Temperatures were documented with temperature-loggers.

Salinity

Different salinities were achieved by adding more or less salts listed for the preparation of artificial seawater (chapter 2.1) by the rule of proportions.

pH

pH was tested from 4 to 9 (4.0, 5.0, 6.0, 6.5, 7.0, 7.5, 8.0, 9.0). Instead of HCO₃⁻, sodium acetate (pH 4-5), MES (pH 6-6.5), HEPES (pH 7-8) and TRIS (pH 9) were used for pH buffering. Artificial seawater was prepared with 10 mM of the respective buffer substance and the pH was adjusted before and after autoclaving by the addition of NaOH or H₂SO₄. Ar or N₂ was used for de-oxygenation. 2.5 mL L⁻¹ 1 M NaHCO₃ was added as carbon source before bottling.

O₂ tolerance

The effect of different O₂ levels onto growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* were investigated. 150 mL serum bottles were filled with 50 mL medium and the remaining 100 mL headspace was flushed with the anoxic gas mixture used for the preparation of anoxic medium (2.1) for 1 minute. No volume (0 Vol% O₂), 5 mL (1%), 20 mL (4%) or the headspace (21%) was exchanged with 0.2 µm filtered breathing air (~ 21% O₂). Complete exchange was done by flushing the headspace with air for 1 minute.

3 Results

3.1 Chapter I: Reduction of MnO_2 coupled to the oxidation of $\text{S}_2\text{O}_3^{2-}$ and H_2S

The original water sample from the Black Sea was supplied with MnO_2 and daily small additions of H_2S to enrich for the metabolism of interest. Subsequently, $\text{S}_2\text{O}_3^{2-}$ was used as electron donor, because it is not toxic even in higher concentrations non-reactive with the MnO_2 used in this work and a suitable electron donor for most sulfur oxidizing bacteria, which can be grown with batch type cultivation. Batch type cultivation with MnO_2 and $\text{S}_2\text{O}_3^{2-}$ was accompanied by a color change of the medium from black to brownish-gray (Fig. 11A and B, bottle photographs). By microscopic inspection of DAPI-stained culture samples, cells appeared to be mostly associated to particles (Fig. 12, 13 and 14). The colonization of particles by *S. marisnigri* ranged from single cells and cell plugs (Fig. 12A) to large-scale occupation (Fig. 12B and C) with sometimes biofilm-like structure (Fig. 12D). Analysis with HIM-SIMS and NanoSIMS showed that the particles covered with bacteria consist of Mn (Fig. 13 and 14).

Detailed imaging of the particulate phase before and after growth of the culture revealed that the change in color is concurrent with a change in the shape and mineralogy of the Mn con-

Figure 11: Bottle photographs, scanning electron micrographs and EDX spectra of the particulate phase before (A) and after growth (B) of *S. marisnigri* cultivated with MnO_2 and $\text{S}_2\text{O}_3^{2-}$.

taining particles. Technical MnO_2 added as electron acceptor had a needle like shape (Fig. 11A, scanning electron micrograph) with no detectable Ca content (Fig. 11A, EDX spectrum), while the particulate phase at the end of bacterial growth consisted of rhombohedral shaped Mn particles (Fig. 11B, scanning electron micrograph) with a high Ca-content (Fig. 11B, EDX spectrum). TIC analysis of the particulate phase after bacterial growth revealed a high content of carbonate (Tab. 20) here referred to as $\text{Mn}(\text{Ca})\text{CO}_3$.

In a time course experiment, the transition of MnO_2 to $\text{Mn}(\text{Ca})\text{CO}_3$ together with the spatial localization of *S. marisnigri* and the elements Mn and Ca was documented using NanoSIMS (Fig. 14). The elements ^{55}Mn , ^{40}Ca and the combined mass of $^{12}\text{C}^{14}\text{N}$ (as indicator for a biological origin) were detected and color coded in green, red and blue, respectively. Cell numbers increased which could be seen by direct cell counting (Fig. 14A) and by higher visual abundance e.g. day 0 compared to day 13 (in Fig. 14, $^{12}\text{C}^{14}\text{N}$ signal, blue).

Figure 12: Epifluorescence images of a *S. marisnigri* culture grown with MnO_2 stained with the DNA dye DAPI at 630x magnification. Scale bars: 20 μm .

S. marisnigri was mostly located at or in the proximity of manganese particles (Fig. 14, day 6). At day 0, no mixed signal of red and green could be seen, which indicated the absence of reduced Mn in $\text{Mn}(\text{Ca})\text{CO}_3$ precipitates. This could also be seen in the absence of particles with a detectable Ca to Mn ratio (Fig 14B, values for day 0 not shown). The Ca to Mn ratio in particles increased (Fig 14B, day 6) and rhombohedral $\text{Mn}(\text{Ca})\text{CO}_3$ precipitates appeared with a mixed color of red and green in the NanoSIMS images. Apparently the $\text{Mn}(\text{Ca})\text{CO}_3$ precipitates grew directly at the surface of MnO_2 particles. The needle shaped MnO_2 particles looked haggard in the time course of the experiment (Fig. 14, day 13, green rod). Analysis of approximately 1000 single particles at day 10, 13 and 17 using automated particle analysis with SEM-EDX revealed a homogenous Ca to Mn ratio among the precipitated particles (Fig. 14B). At day 3 and 6, the Ca to Mn ratio of the particles is more heterogeneous and the resulting slope like plot did not show a plateau as it can be seen at day 10, 13 and 17 (Fig. 14B). Because the $\text{Mn}(\text{Ca})\text{CO}_3$ precipitates grew at the MnO_2 particle surfaces, the automated particle analysis might be unable

Figure 14: Mn particle dynamic in the growth phase of *S. marisnigri*. Growth of *S. marisnigri* (A, open circles, solid line) is accompanied with the increase of the Ca to Mn ratio in single particles (B) from day 3 to day 10 where growth stopped. Precipitation of cube shaped $\text{Mn}(\text{Ca})\text{CO}_3$ precipitates can be traced in the NanoSIMS images by the portion of red (Ca) to green (Mn) color. *S. marisnigri* ($^{12}\text{C}^{14}\text{N}$ – blue) is more abundant at e.g. day 13 compared to day 0 as it can be expected by the direct cell counting (A). Analysis of up to 1000 single particles using SEM-EDX revealed the homogeneity of the Ca to Mn ratio in different particles at day 10 without major changes afterwards (B).

to distinguish between Mn(Ca)CO₃ precipitates and MnO₂ particles at day 3 and 6. After the complete growth of *S. marisnigri* at approximately day 10, no drastic change in the particulate Ca to Mn ratio was detectable (Fig. 14B). This indicates that the reduction of MnO₂ by *S. marisnigri* was fostering the succession of the observed Mn particles in this experiment, leading to the formation of Mn(Ca)CO₃ precipitates with a homogenous Ca to Mn ratio.

Cultivation of *S. marisnigri* with MnO₂ and S₂O₃²⁻

The reduction of MnO₂ with S₂O₃²⁻ as electron donor by *S. marisnigri* was accompanied by the complete oxidation of S₂O₃²⁻ to SO₄²⁻ with a stoichiometry of 1:2 (Fig. 15A) following Eq. 3.12:

No detectable accumulation of S⁰ or SO₃²⁻ was observed. The stoichiometry between S₂O₃²⁻ and MnO₂ was 1:3.7, a bit lower than it would have been expected based on Eq. 3.13, but relatable because some reducing equivalents were needed to maintain CO₂ fixation according to Eq. 3.14.

Until day 6, the concentration of particulate Mn (Mn_{part.}) decreased concurrent with an equal increase in dissolved Mn (Mn_{diss.}) species (Fig. 15B). After 6-7 days, the precipitation of rhombohedral Mn(Ca)CO₃ was documented by a steady increase in the particulate Ca-content (Fig. 15B, bars) and again increasing concentration of Mn_{part.}. With a mean Ca to Mn ratio of 0.19 ± 0.03 (N = 77) in single rhombohedral Mn(Ca)CO₃ precipitates, the amount of reduced Mn in the particulate phase (Mn_{part.(red)}) was calculated with Eq. 2.8 (Fig. 15B, dashed blue line). No changes in Mn and S species were detectable in the abiotic control (Fig. 15C).

Thereby it was shown, that MnO₂ was almost completely reduced and transformed to Mn(Ca)CO₃, following the stoichiometry between S₂O₃²⁻ oxidation and MnO₂ reduction. In

Figure 15: Growth of *S. marisnigri* with MnO_2 and $S_2O_3^{2-}$. A, oxidation of $S_2O_3^{2-}$ resulted in growth and accumulation of SO_4^{2-} in a final ratio of 1:2. B, reduction of MnO_2 results in the equal increase in dissolved Mn ($Mn_{diss.}$) until day 6, almost exclusively reactive Mn ($dMn_{react.}$, putative Mn^{3+}). With the precipitation of $Mn(Ca)CO_3$, indicated by the increase in particulate Mn and increasing particulate Ca to Mn ratio (bars). C, abiotic controls show no changes in the time course of the experiment. D, pH increase due to Mn reduction and decrease at the time $Mn(Ca)CO_3$ precipitates.

accordance to Eq. 3.13 and 3.15, the pH decreased from 7.65 at day 7 to 7.3 towards day 10-11 (Fig. 15D), due to the precipitation of $Mn(Ca)CO_3$.

In theory, results shown in Fig. 15 could also be attributed to a biological disproportionation of $S_2O_3^{2-}$ to H_2S and SO_4^{2-} (Eq. 3.16) with a subsequent chemical oxidation of H_2S with MnO_2 (Tab. 2).

This is unlikely and will be discussed in more details in chapter 3.3.3.

Cultivation of *S. marisnigri* with MnO_2 and a constant supply of H_2S

Growth of *S. marisnigri* with MnO_2 and a constant supply of H_2S resulted in the accumulation of SO_4^{2-} concurrent with increasing cell numbers, with negligible concentrations of S^0 ,

whereas in the sterile control S^0 accumulated with just minor concentrations of SO_4^{2-} (Fig. 16). In the biological treatment (Fig. 16B) 4 times more total dissolved Mn was produced compared to the sterile control (Fig. 16D), according to Eq. 3.17 and Eq. 3.18, respectively.

The summed concentration of S^0 and SO_4^{2-} between the biological treatment (Fig. 16A) and the sterile control (Fig. 16C) was unequal. Nevertheless, the filling levels of the bottles were equal and the setup of the experiment (see chapter 2.12.2) excluded dissimilarities regarding

Figure 16: *S. marisnigri* and a sterile control were cultivated with MnO_2 and H_2S was constantly supplied via a peristaltic pump out of a Na_2S stock solution (Fig. 9). Growth of *S. marisnigri* was concurrent with the production of SO_4^{2-} (A) and the production of dissolved Mn (B), while the concentration of S^0 remained low. In the sterile control, S^0 instead of SO_4^{2-} accumulated (C) and the dissolved Mn is accumulating in a lower amount (D). Increasing Ca content in the particulate phase (B, bars) together with decreasing concentrations of dissolved Mn indicate the precipitation of $\text{Mn}(\text{Ca})\text{CO}_3$.

H₂S addition between the bottles. Therefore, about 0.8 mM S was missing in S-pools others than S⁰ and SO₄²⁻ in the sterile treatment. After day 5, the factor in the total dissolved Mn concentration between the biological and the sterile treatment exceeds 4 and reached 4.97 at day 7, which indicated the presence of a sulfur species with a redox state below 0, e.g. polysulfides (S_n²⁻) or unreacted H₂S in the presence of MnO₂ in the sterile control.

The data resulted from growth of *S. marisnigri* with MnO₂ and a constant supply of H₂S (Fig. 16) could also be explained by an incomplete abiotic oxidation of H₂S with MnO₂ to e.g. S⁰ (Tab. 2), followed by a biological oxidation to SO₄²⁻ or a disproportionation of S⁰ to H₂S and SO₄²⁻. To provide evidence, that *S. marisnigri* did not depend on S-compounds with intermediate oxidation state and is capable of oxidizing H₂S directly, several experiments were conducted.

Cultivation of *S. marisnigri* and *S. baltica* with NO₃⁻ and H₂S

S. marisnigri and *S. baltica* were cultivated with NO₃⁻ instead of MnO₂ as terminal electron acceptor. NO₃⁻ is non-reactive with H₂S and can be used as terminal electron acceptor by *S. marisnigri* and *S. baltica* (see chapter 3.3.1). H₂S was added several times a day in small amounts out of a Na₂S stock solution (Fig. 17, grey dots). Under these culturing conditions, *S. marisnigri* and *S. baltica* grew (Fig. 17, open circles, dashed line) and H₂S concentrations remained undetectable (open diamonds). In the corresponding controls H₂S accumulated steadily (solid diamonds) according to the additions of H₂S (grey dots).

Cultivation of *S. marinsigri* with MnO₂ and either H₂S or S-products of a chemical oxidation of H₂S with MnO₂

In another approach addressing the same question, *S. marisnigri* was cultivated with MnO₂ as terminal electron acceptor and the electron donor was supplied daily as described above by multiple small additions of different solutions. The first electron donor solution was a pure Na₂S stock solution (H₂S); the other was treated with MnO₂ to generate oxidation products of S with different oxidation states (Mn/H₂S) before it was added to *S. marisnigri*. Chemical

Figure 17: Cultivation of *S. marisnigri* and *S. baltica* with NO_3^- as terminal electron acceptor and H_2S as electron donor. H_2S was added in small single additions resulting in micromolar concentrations out of a Na_2S stock solution (grey dots). Both strains showed growth (open circles, dashed line) and H_2S remained constantly low (open diamonds, solid line). In the sterile controls, H_2S accumulated steadily according to the additions of H_2S (closed diamonds, solid line).

analysis of the two electron donor solutions showed the following composition. The H_2S solution had a concentration of 10.9 mM with no detectable S compounds with other oxidation state. The Mn/ H_2S solution had a concentration of 9.5 mM and consisted of S^0 (96.1%), $\text{S}_2\text{O}_3^{2-}$ (3.6%) and SO_4^{2-} (0.3%). Growth of *S. marisnigri* was observed under both culturing conditions (Fig. 18). When H_2S was added directly as electron donor (left), growth rate and yield were increased in comparison to the parallels treated with pre-reacted H_2S

Figure 18: *S. marisnigri* in triplicates. Addition of H_2S , pre-reacted with MnO_2 (right) or not (left).

(right) within the 9 days of experiment. Samples for SO_4^{2-} were taken approximately 1 week after the end of the electron donor additions and SO_4^{2-} concentrations of $1.28 \text{ mM} \pm 0.04$ (Mn/ H_2S) and $1.54 \text{ mM} \pm 0.04$ (H_2S) were measured. With pre-reacted H_2S (Fig. 18, right), the growth yield was approximately 60% lower compared to the parallel where H_2S was added directly (Fig. 18, left). This difference cannot be attributed to the overall lower addition of electron donor. Unfortunately, no cell numbers were estimated after day 9. Therefore it may be possible, that the growth rate of *S. marisnigri* was lower when pre-reacted H_2S was provided, but cell numbers kept increasing after day 9 reaching an overall comparable yield.

H_2S oxidation rates in a temperature gradient

Cell specific H_2S oxidation rate of *S. marisnigri* and H_2S oxidation rates in sterile controls in the presence of MnO_2 were estimated in a temperature gradient ranging from 3 °C to 18 °C (Fig. 19 – for more details see also chapter 3.2.1). The chemical oxidation rate responded linearly to changes in temperature, in contrast to the biological oxidation rate per cell, which responded in an exponential like decrease towards 3 °C, indicating an enzymatic related inhibition of the H_2S oxidizing activity due to low temperatures.

Figure 19: Reaction rate coefficient k in the temperature range from 3 to 18 °C for the oxidation of H_2S with or without *S. marisnigri*. In the sterile control, the reaction rate responded linearly to the change of the temperature. In the presence of *S. marisnigri* the reaction rate coefficient responded in an exponential like manner, reflecting a putative enzymatically catalyzed oxidation of H_2S .

3.2 Chapter II: Influence of a biological H₂S oxidation on the geochemical structure of the Black Sea suboxic zone.

In the Black Sea suboxic zone, H₂S is consumed up to tens of meters below the first detectable concentrations of O₂ or NO₃⁻. The only available compound for H₂S oxidation would be MnO₂, which can be transported by gravitational sinking from the oxic, overlying water body, to the sulfidic water below.

3.2.1 Estimation of a biological H₂S oxidation rate in the presence of MnO₂

Experiments with *S. marisnigri* were done to obtain a H₂S-oxidation rate represented by a bacterium originating from the lower boundary of the Black Sea suboxic zone. To enable the measurement of a H₂S oxidation rate by *S. marisnigri* in the presence of MnO₂, the concurrent chemical oxidation of H₂S with MnO₂ had to be determinable and in best case constant to be subtracted from the overall oxidation rate. Therefore, the second order chemical reaction between MnO₂ and H₂S had to be simplified. By adding MnO₂ in excess, the reaction order was changed from a second order to a pseudo-first order reaction. Thereby, the reaction rate was only depending on the concentration of H₂S and not both, the surface area of MnO₂ and the concentration of H₂S.

This solved several difficulties:

- i. The chemical reaction rate was only depending on the concentration of H₂S.
- ii. The chemical oxidation of H₂S was proceeding with the maximum possible reaction rate at the given ambient conditions of pH, temperature and mineralogical structure of the provided MnO₂.
- iii. Only the concentration of H₂S had to be recorded, which was possible with high resolution by the use of H₂S microsensors.
- iv. The rate could be determined and subtracted from a rate which was determined in the presence of *S. marisnigri*.

S. marisnigri was cultivated with $\text{S}_2\text{O}_3^{2-}$ as electron donor and MnO_2 in 10-fold excess. During the growth phase of 12 days, the cell counts of *S. marisnigri* exceeded 10^7 cells mL^{-1} , $\text{S}_2\text{O}_3^{2-}$ was depleted and the remaining concentration of MnO_2 was high enough to result in pseudo-first order mode of reaction with single additions of H_2S (Tab.21 – compare sterile control with pasteurized culture treatment). Pulses of H_2S were added to the medium and the disappearance of H_2S was recorded with a H_2S microsensor (Fig. 20). Afterwards, the medium was pasteurized or poisoned with sodium azide to inhibit *S. marisnigri* and further pulses of H_2S were added. The concentration of H_2S was normalized to the initial concentration (Fig. 20A) of H_2S for each single addition and plotted against time. The reaction rate coefficient k (time^{-1}) was calculated for each addition of H_2S by fitting the equation in Fig. 20 to the respective plot (Fig. 20B and C), where $C_{\text{H}_2\text{S}(t)}$ is the concentration of H_2S at time t , $C_{\text{H}_2\text{S}(0)}$ is the initial concentration of H_2S , t the time in minutes and a the variable to adjust for the y-intercept. Consecutive additions of H_2S resulted in the reproducible exponential like disappearance of H_2S (Fig. 20, top) with comparable reaction rate coefficients, which are summarized in Tab. 21. Addition of sodium azide reduced the H_2S oxidation rate by approximately

Figure 20: Experimental approach to determine H_2S oxidation rates. Chronological sequence of consecutive additions and adjacent consumptions of micromolar concentrations of H_2S (top). After several additions, the medium was either pasteurized or poisoned with sodium azide (red arrow) and another three additions were recorded subsequently. Each addition was evaluated separately. A, normalization of one addition to the initial value. B, non-linear least square fit to the shown equation. C, solving the equation after k .

Table 21: Reaction rate coefficient k as a function of different types of inhibition in the presence or absence of *S. marisnigri*. Cell numbers of *S. marisnigri* were $5.87 \times 10^{10} \text{ L}^{-1}$, $4.71 \times 10^{10} \text{ L}^{-1}$ and $5.10 \times 10^{10} \text{ L}^{-1}$ in the parallels 1, 2 and 3, respectively. 0 = no inhibition; A = inhibition with sodium azide; P = inhibition with pasteurization.

	Inhibition	Parallel	$k \text{ (min}^{-1}\text{)}$	SD	N
<i>S. marisnigri</i>	0	1	-0.414	0.044	7
	A	1	-0.309	0.011	3
	0	2	-0.391	0.026	8
	P	2	-0.081	0.007	3
	0	3	-0.419	0.034	8
	P	3	-0.080	0.004	3
Sterile control	0	1	-0.090	0.004	5
	A	1	-0.071	0.003	2
	0	2	-0.098	0.009	5
	P	2	-0.077	0.001	3
	0	3	-0.073	0.005	5
	P	3	-0.079	0.004	3

25% while pasteurization reduced the oxidation rate to the level of the chemical background reaction (Tab. 21 - compare with the sterile control measurements). Little to no effect of the addition of sodium azide or pasteurization on the reaction rate of the sterile control was observed.

3.2.2 Numerical modeling

To implement these H_2S oxidation rates of *S. marisnigri* into a numerical model, a biological reaction rate coefficient k_{bio} had to be calculated according to Eq. 3.19,

$$k_0 - k_{\text{A or P}} = k_{\text{bio(A) or bio(P)}} \quad 3.19$$

where k_0 is the reaction rate coefficient in the presence of *S. marisnigri* before inhibition, k_{A} the reaction rate coefficient after the addition of sodium azide, k_{P} the reaction rate coefficient after pasteurization and $k_{\text{bio(A)}}$ and $k_{\text{bio(P)}}$ the respective resulting biological reaction rate coefficients.

In the following, $k_{\text{bio(A)}}$ and $k_{\text{bio(P)}}$ were calculated per second and per cell to implement the value into the numerical model. Abundances of *Epsilonbacteraeota* in Black Sea waters of the

suboxic zone needed for the model were kindly provided by Klaus Jürgens. The cell abundances of *Epsilonbacteraeota* were estimated by fluorescence in situ hybridization (FISH) staining with probe EPS914. Cellular abundance of *Epsilonbacteraeota* did match the natural abundance of *Sulfurimonas* spp. in the Black Sea suboxic zone closely. This has been shown by Dr. Thomas Schott and Prof. Dr. Klaus Jürgens (personal communication). With 16S rRNA amplicon sequencing and metatranscriptomic analysis it was shown that over the entire suboxic zone up to 97% of all *Epsilonbacteraeota* reads belong to the genus *Sulfurimonas*, which is almost exclusively expressing the sulfide:quinone oxidoreductase gene (*sqr*) in the depth of H₂S removal. Therefore, applying the H₂S oxidation rates measured with *S. marisnigri* in pure culture to the abundance of *Epsilonbacteraeota* is reflecting the natural setting quite well.

For the model approach it is assumed that Mn oxides are constantly provided in sufficient amount by gravitational sinking. The H₂S profiles shown in Figure 21 (A and D) are obtained after a 3 year time run of the model. H₂S concentration profiles modeled with $k_{\text{bio(A)}} = -3.16 \times 10^{-14} \text{ L cell}^{-1} \text{ s}^{-1}$ and $k_{\text{bio(P)}} = -1.05 \times 10^{-13} \text{ L cell}^{-1} \text{ s}^{-1}$ (A and D, respectively) resulted in a sharp drop to 0 μM H₂S comparable to the measured H₂S profile in the Black Sea (Fig. 2A and B, Fig. 21, grey dots). The overall H₂S oxidation rate (Fig. 21B and E) exceeded $1 \times 10^{-6} \mu\text{M s}^{-1}$ and $1.5 \times 10^{-6} \mu\text{M s}^{-1}$ and the cell specific oxidation rate (Fig. 21C and F) exceeded $2 \times 10^{-14} \mu\text{M s}^{-1}$ and $4 \times 10^{-14} \mu\text{M s}^{-1}$ based on $k_{\text{bio(A)}}$ and $k_{\text{bio(P)}}$, respectively. Based on the work of Yao & Millero (1993) chemical reaction rates of MnO₂ and H₂S were calculated at 10 °C and pH 7. With 10 nM MnO₂ $9.53 \times 10^{-8} \mu\text{M H}_2\text{S s}^{-1}$ are oxidized at a constant H₂S concentration of 1 μM . The model was run with a chemical k value (k_{chem}) of $-9.53 \times 10^{-8} \text{ s}^{-1}$. Because the steep H₂S profile measured in situ by Schulz-Vogt et al. (2019) (Fig. 21, grey dots), oxidation rates were with k_{chem} were calculated at the chemocline and overlying waters (Fig. 21G). With these settings, the suboxic zone collapsed and H₂S was not retained at approx. 105 m water depth.

Figure 21: Modeled H_2S concentration (red dots) profiles based on $k_{\text{bio(A)}}$ (A), $k_{\text{bio(P)}}$ (D) and k_{chem} (G) and resulting total (B, E and G) and cell specific (C and F) H_2S oxidation rates (purple dots) in the suboxic zone of the Black Sea. Data for the in situ H_2S profile (grey dots) were taken from Schulz-Vogt et al. (2019). Abundances of *Epsilonbacteraeota* from the Black Sea (large blue dots) were kindly provided by Prof. Dr. Klaus Jürgens, and interpolated (small blue dots). Plots A to F are shown in steady state. Chemical H_2S oxidation rate (G) calculated at 10 °C, pH 7 and 10 nM MnO_2 (Yao & Millero, 1993).

3.3 Chapter III: Ecological niches of the newly isolated *Sulfurimonas* strains in comparison to *S. gotlandica*.

Two new isolates, one originating from the Black Sea named *Sulfurimonas marisnigri* and one from the Baltic Sea named *Sulfurimonas baltica*, together with the already validly described closely related species *Sulfurimonas gotlandica* GD1, were investigated regarding dissimilatory metabolism, assimilatory metabolism and abiotic factors influencing growth.

3.3.1 Dissimilatory metabolism - electron acceptors

Oxygen (O₂)

The ability to utilize O₂ as electron acceptor was tested along with the putative inhibiting effects of O₂ on growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* by adjusting the O₂ content in the headspace of partially filled serum bottles, but no further electron acceptor was added. All strains showed growth with O₂ provided as electron acceptor (Fig. 22). In contrast to *S. gotlandica*, *S. marisnigri* and *S. baltica* were unable to grow at the highest O₂ content of 21%. No major difference in dissolved oxygen concentration at 21% O₂ in the headspace with *S. marisnigri* ($-2 \mu\text{M} \pm 22$) or *S. baltica* ($-6 \mu\text{M} \pm 36$) was detectable in comparison to the control, whereas the difference in dissolved O₂ concentration was clearly higher for *S. gotlandica* ($-179 \mu\text{M} \pm 81$) shown in Tab. 22.

No visible differences in growth could be seen for 4% and 1% O₂ with *S. marisnigri* and *S. baltica*. *S. gotlandica* showed best growth at 4% followed by 1% and 21% O₂. At 0% O₂, all

Figure 22: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* with O₂ as electron acceptor at different O₂ contents in the headspace.

Table 22: Difference in the dissolved oxygen concentration after complete growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* with O₂ as sole electron acceptor.

Strain	% O ₂ (N)	ΔO ₂ (μM)	SD
<i>S. marisnigri</i>	21 (3)	-2	22
	4 (3)	-45	1
	1 (3)	-30	1
	0 (2)	-2	0
<i>S. baltica</i>	21 (3)	-6	36
	4 (3)	-55	2
	1 (3)	-26	2
	0 (3)	-2	0
<i>S. gotlandica</i>	21 (3)	-179	81
	4 (3)	-49	1
	1 (3)	-21	1
	0 (3)	-2	1

strains showed increasing but overall lower cell numbers, which was supported by decreased dissolved oxygen concentrations in the serum bottles after growth. Because no reducing agent was used for the preparation of anoxic medium, small contaminations of O₂ could not be excluded. Between 1.5 and 10 μM dissolved O₂ were measured in un-inoculated serum bottles with 50 mL medium and 100 mL headspace volume.

Nitrate (NO₃⁻)

All three strains showed growth with NO₃⁻ provided as electron acceptor (Fig. 23), but the overall growth yield of *S. marisnigri* and *S. baltica* is more than one order of magnitude lower compared to *S. gotlandica* under the same culturing conditions. In a more detailed approach, growth of *S. marisnigri* with S₂O₃²⁻ and NO₃⁻ was shown to be concurrent with the production of NO₂⁻ and stoichiometric removal of NO₃⁻ (Fig. 24). The addition of MnO₂ at day 22, after growth stopped at day 8-9 due to the depletion of NO₃⁻ resulted in subsequent increasing cell numbers in the presence of approximately 4.5 mM NO₂⁻ indicating that *S. marisnigri* is not inhibited by about 4 mM NO₂⁻.

Nitrite (NO₂⁻)

No growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* was observed with NO₂⁻ as electron acceptor within the time course of 7 days (Fig. 25). Because the growth yields of *S. baltica*

Figure 23: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* with NO_3^- as sole electron acceptor.

Figure 24 Growth of *S. marisnigri* with NO_3^- and a surplus of $\text{S}_2\text{O}_3^{2-}$ in triplicates. NO_3^- is stoichiometrically reduced to NO_2^- . Growth went on after MnO_2 was added at day 22 (red arrow).

Figure 25: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* with NO_2^- as sole electron acceptor. Mind the different y-axis and low values.

and *S. marisnigri* cultivated with NO_3^- and $\text{S}_2\text{O}_3^{2-}$ were comparable (Fig. 23), *S. baltica* might as well reduce NO_3^- to NO_2^- and not further to N_2 . *S. gotlandica* might have started growing but a prolonged sampling would have been necessary to assure the trend towards day 7 (Fig. 25).

Metal oxides

All three strains were cultivated with different iron sources and *S. gotlandica* was additionally cultivated with MnO_2 . As potential electron acceptor the iron oxides FeCl_3 , Fe_2O_3 , freshly precipitated amorphous FeOOH and goethite ($\alpha\text{-FeOOH}$) together with $\text{S}_2\text{O}_3^{2-}$ as electron

donor were tested. In a first approach, all strains were cultivated with Fe_2O_3 , FeCl_3 and *S. gotlandica* additionally with MnO_2 as electron acceptors (Fig. 26).

Unfortunately, no positive or negative controls were prepared for this experiment. All strains showed increasing cell numbers under these culturing conditions. Interestingly, cells of all three *Sulfurimonas* strains did not show attachment to any of the tested metal oxide particles examined by DAPI stained epifluorescence microscopy and SEM. To exclude a potential growth of the three strains with $\text{S}_2\text{O}_3^{2-}$ and O_2 contaminations in the medium, two bottles were prepared in parallel with just $\text{S}_2\text{O}_3^{2-}$. Putative O_2 contaminations were eliminated chemically in one bottle by the addition of cysteine 7 days before cells were added (Fig. 26, Control + Cys), the other remained untreated (Fig. 26, Control). This was done for *S. marisnigri* and *S. gotlandica*. Growth was detectable within 7 days when no cysteine was added in contrast to the parallel treated with cysteine, where no growth was observed. Additionally, concentrations of dissolved Fe and Mn were quantified since the reduction of metal oxides should have led to the increase in dissolved phases of the respective metal. No dissolved Fe could be detected in bottles cultivated with Fe_2O_3 and dissolved Mn concentration was below $25\ \mu\text{M}$, which is far too low to be attributed to a dissimilatory Mn reduction by *S. gotlandica*. Further, no indication of a particulate reduced Mn phase (see chapter 3.1) was observed by eye or

Figure 26: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* cultivated with different metal oxides as electron acceptors. Control measurements were done without the addition of a metal oxide electron acceptor (Control) and cysteine was added to parallel control incubations (Control + Cys) to determine the influence of ambient O_2 contaminations on growth of *S. marisnigri* and *S. gotlandica*.

scanning electron microscopy when *S. gotlandica* was cultivated with MnO₂. In a second approach, all strains were cultivated with freshly precipitated amorphous FeOOH or goethite (α -FeOOH). No growth or attachment to the Fe oxide particles was observed.

3.3.2 Dissimilatory metabolism - electron donors

Elemental sulfur (S⁰)

Freshly prepared colloidal elemental sulfur (S⁰) was tested as potential electron donor for growth of *S. marisnigri*, *S. baltica* and *S. gotlandica*. All strains showed growth with S⁰ as electron donor with a 1 day lag phase (Fig. 27) and the growth yield of all strains was comparable. No H₂S smell was noticeable at the end of the experiment after the bottles were opened.

Sulfite (SO₃²⁻)

Adding SO₃²⁻ as electron donor did not result in growth of *S. marisnigri* or *S. baltica* (Fig. 28). *S. gotlandica* showed growth until day 7 followed by an unexpected sharp drop from 8 x 10⁷ cells mL⁻¹ to 2-3 x 10⁶ cells mL⁻¹.

Figure 27: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* in triplicates with colloidal sulfur (S⁰) added as electron donor.

Figure 28: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* with sulfite (SO₃²⁻) added as electron donor.

Hydrogen (H₂)

Hydrogen was provided by flushing the bottle headspaces with H₂ gas. To exclude any negative effects of H₂ in the headspace on growth, a positive control containing a H₂ filled headspace as well as S₂O₃²⁻ provided as electron donor in the medium was prepared. A negative control contained neither H₂ in the bottle headspace, nor S₂O₃²⁻ was added as electron donor. All strains showed growth in the presence of H₂ in the bottle headspace (Fig. 29). Cell numbers of *S. gotlandica* were close to one magnitude higher than cell numbers of *S. marisnigri* and *S. baltica* after 14 days of growth. No growth was observed in negative controls.

Organic carbon

To test the ability of *S. marisnigri*, *S. baltica* and *S. gotlandica* to respire organic carbon, a mixture of acetate (C₂H₄O₂), propionate (C₃H₆O₃) and succinate (C₄H₆O₄) was supplied as electron donors (Fig. 30). Growth was not observed for *S. marisnigri* and *S. baltica*, and cell

Figure 29: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* with hydrogen (H₂) added as electron donor. Positive controls were prepared by adding S₂O₃²⁻ as electron donor next to H₂. Negative controls were prepared by adding neither H₂ to the bottle head space nor S₂O₃²⁻ as additional electron donor.

Figure 30: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* with an organic carbon mixture containing acetate, propionate and succinate added as electron donor. With *S. marisnigri* as an example it can be seen, that multiple transfers might be necessary to exclude growth.

abundance remained low. *S. gotlandica* showed growth to a maximum of about 3.5×10^5 cells mL⁻¹ at day 4, which is low compared to the growth yield on reduced sulfur species.

3.3.3 Disproportionation of S⁰ and S₂O₃²⁻

The disproportionation of S⁰ or S₂O₃²⁻ leads to the production of H₂S according to Eq. 3.20 and 3.21 (Finster et al., 1998), which itself can react chemically with MnO₂ (Yao and Millero, 1993, Tab. 2) used for cultivation as electron acceptor for *S. marisnigri* and *S. baltica*.

To test the ability of the three strains to disproportionate S₂O₃²⁻ and S⁰ the respective compound was added without the addition of a further electron acceptor. All strains showed growth under these culturing conditions (Fig. 31).

However, the overall growth yield could also be attributed to the oxidation of S⁰ and S₂O₃²⁻ with ambient O₂ contaminations as electron acceptor, since the 0% O₂ negative control used

Figure 31: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* cultivated with S⁰ or S₂O₃²⁻ and no further addition of an electron donor.

Figure 32: *S. marisnigri* grown with S₂O₃²⁻ and MnO₂. Concentration of S₂O₃²⁻ (black solid circles, solid line) remained unchanged after complete growth of *S. marisnigri* (crosses, dashed line) and depletion of MnO₂ approximately at day 4 to 5 according to the color shift to brownish-grey.

in the experiments with O_2 as potential electron acceptor shows comparable growth yields of $2-3 \times 10^6$ cells mL^{-1} (Fig. 22). Further, no smell of H_2S was noticeable after the bottles were opened at the end of growth. To address this critical issue in more detail, *S. marisnigri* was grown with MnO_2 and a slight surplus of $S_2O_3^{2-}$ (Fig. 32). At day 4 to 5 the color of the bottles changed from black to brown greyish which typically indicates the depletion of MnO_2 (see chapter 3.1). Concentrations of $S_2O_3^{2-}$ remained constant after the depletion of MnO_2 at approximately day 5-6 indicating no disproportionation of $S_2O_3^{2-}$.

3.3.4 Sulfate (SO_4^{2-}) - reduction

To test for SO_4^{2-} reduction a mixture of acetate, propionate and succinate was added to standard medium enriched in SO_4^{2-} added as $MgSO_4$. No growth of *S. baltica* and *S. gotlandica* was observed (Fig. 33). Increasing but overall low cell numbers of *S. marisnigri* were observed. No smell of H_2S was noticeable after the bottles were opened.

Figure 33: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* cultivated with SO_4^{2-} and an organic carbon mixture of acetate, propionate and succinate.

3.3.5 Fermentation

To test for fermentation of organic C, a mixture of acetate, propionate and succinate was added to standard medium. All three strains showed little to no growth under these culturing conditions (Fig. 34). For *S. marisnigri* the first transfer and for *S. baltica* and *S. gotlandica* the second transfer is displayed. The first transfers of *S. baltica* and *S. gotlandica* resulted in cell numbers one magnitude higher compared to the second transfer, which might have also been the case for *S. marisnigri*, if another transfer would have been made.

Figure 34: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* cultivated with a mixture of acetate, propionate and succinate without any further electron acceptor or donor. Cellular abundance of *S. marisnigri* of the first transfer is shown. For *S. baltica* and *S. gotlandica* the second transfer in the respective growth medium is shown.

3.3.6 Assimilatory metabolism

N₂ - fixation

The ability of *S. marisnigri*, *S. baltica* and *S. gotlandica* to fix molecular N₂ as N-source was investigated by omitting the addition of NH₄Cl as N-source to the medium (Fig. 35). N₂ should have been available in sufficient amounts, because the gas mixture used to purge O₂ during medium preparation and to prevent O₂ contamination in the bottling process consists of 80 vol.% N₂. No NO₃⁻ was added as electron acceptor for the growth of *S. gotlandica* because it could be used as nitrogen source, too. Thus, O₂ was provided as electron acceptor by replacing the headspace volume with normal breathing air. *S. gotlandica* showed growth in the respective experiment when NH₄Cl was present and O₂ was provided as sole electron acceptor (Fig. 40 and 22). *S. marisnigri* and *S. baltica* showed growth under these culturing conditions in the absence of NH₄Cl (Fig. 35, blue graphs). No growth of *S. gotlandica* was observed under these culturing conditions.

Figure 35: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* in the absence of NH₄Cl with only N₂ provided as the N source. For *S. gotlandica*, NO₃⁻ was substituted with O₂ as electron acceptor by exchanging the headspace with sterile breathing air.

Organic carbon (C-org) assimilation

To test for the ability to use organic carbon as C-source (C-heterotroph) growth medium was prepared with N₂ or Ar gas instead of a gas mixture containing CO₂ and HEPES was used as pH buffer. As potential C-sources acetate, propionate and succinate were tested next to a positive control where HCO₃⁻ was added and a negative control where no carbon source was provided (Fig. 36). *S. marisnigri* did not show growth with acetate and propionate in the growth phase of 7 days. In the treatment containing succinate the cell numbers were slightly higher compared to the negative control (6.03×10^5 cells mL⁻¹ to 4.84×10^5 cells mL⁻¹, respectively). Therefore, the difference can be considered as too low to decide whether growth was positive or not. *S. baltica* showed growth with all tested carbon sources. Highest cell numbers after the growth period of 7 days were measured with acetate (4.10×10^7 cells mL⁻¹) and succinate (3.81×10^7 cells mL⁻¹) about 30% more compared to the positive control (2.93×10^7 cells mL⁻¹). Cell numbers with propionate were slightly lower after 7 days of growth (1.19×10^7 cells mL⁻¹). *S. gotlandica* did not show growth with the tested carbon sources.

Figure 36: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* with C provided exclusively in the form of organic carbon compounds.

Polyphosphate (polyP) accumulation

To quantify the amount of phosphorus accumulated as polyP in *S. marisnigri*, cells of a grown culture were separated into polyP bearing (polyP⁺) and polyP free (polyP⁻) cells by specific staining with the antibiotic tetracycline and fluorescence-activated cell sorting. The P content of the sorted samples with known cell concentrations was estimated with ICP-MS. The quan-

tity of P accumulated as polyP in a polyP+ cell was calculated by subtracting the mean P content of a polyP- cell from the mean P content of a polyP bearing cell. With this approach a content of 7.54×10^{-18} kg P cell⁻¹ (7.54 fg P cell⁻¹) or 2.43×10^{-16} mol P cell⁻¹ (0.243 fmol P cell⁻¹) stored as polyP was estimated for *S. marisnigri*.

3.3.7 Abiotic factors influencing growth

In a natural environment, bacteria often have to face geochemical gradients which in some cases are changing on short time scales. Next to the availability of energy sources and nutrients, many abiotic factors influence growth of bacteria. In the following, the influence of temperature (0 °C – 40 °C), salinity (5 – 60), pH (4 – 9) and the presence of O₂ on growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* were investigated. The standard conditions for experiments shown here, if not mentioned otherwise, were anoxic medium prepared as described in the material and methods section 2.1, addition of thiosulfate (S₂O₃²⁻) as electron donor, manganese oxide (MnO₂) for *S. marisnigri* and *S. baltica* or nitrate (NO₃⁻) for *S. gotlandica* as electron acceptor, and dark incubation at 10 °C.

Temperature

S. marisnigri and *S. gotlandica* grew from 0 °C to 25 °C, with optimal growth at 20 °C. *S. baltica* grew from 0 °C to 20 °C and optimal growth was observed at 15 °C, slightly lower in comparison to *S. marisnigri* and *S. gotlandica*. All three strains can be considered as psychrotolerant species (Fig. 37).

Salinity

All three strains treated in this work were isolated from brackish environments. *S. marisnigri* was isolated from the Black Sea and *S. baltica* and *S. gotlandica* from the Baltic Sea, at salinities of 21, 14 and 13, respectively. Growth of all strains between a salinity of 5 and 60 was tested (Fig. 38). *S. baltica* and *S. gotlandica* grew from salinities of 5 to 40 with optimal growth at rates of 1.66 d⁻¹ and 1.13 d⁻¹ at a salinity of 21 and 14, respectively. *S. marisnigri*

grew from salinity 10 to 40 with optimal growth at a rate of 1.01 d⁻¹ at a salinity of 25. No growth was observed at a salinity of 60.

pH

To investigate the influence of a different pH on growth of the three strains, medium was prepared with a defined pH from pH 4 to pH 9 (Fig. 39). *S. marisnigri* showed growth from pH 6.5 to 9 with the highest growth rates at pH 7.5 and 8. *S. baltica* showed growth from pH 7 to pH 8 with an optimum between pH 7 and 7.5 and *S. gotlandica* showed growth from pH 6.5 to pH 8 with highest growth rates between pH 7 and 8.

Figure 37: Growth rates of *S. marisnigri*, *S. baltica* and *S. gotlandica* in the temperature range from 0 °C to 30 °C. No growth was observed with temperature exceeding 25 °C.

Figure 38: Growth rates of *S. marisnigri*, *S. baltica* and *S. gotlandica* in the salinity range from 5 to 40. No growth was observed at a salinity of 60.

Figure 39: Growth rates of *S. marisnigri*, *S. baltica* and *S. gotlandica* in the pH range from 6 to 9 in triplicates. One replicate of *S. gotlandica* at pH 6.5 did not grow and the bar represents the mean value and standard deviation of 2 values. No growth was observed below pH 6.5.

Oxygen tolerance

Species of the genus *Sulfurimonas* are commonly found in or next to sulfidic environments with often frequently changing redoxconditions. Cultured representatives of the genus *Sulfurimonas* are to the most extent tolerant to oxygen and predominantly capable of utilizing O₂ as terminal electron acceptor for growth (Han and Perner, 2015).

To investigate whether the presence of dissolved O₂ influences the growth of the three strains, serum bottles were partially filled and the O₂ content in the headspace was adjusted by exchanging a portion of the headspace with sterile filtered air. By this, headspaces with 0%, 1%, 4% and 21% vol.% O₂ were established. In contrast to chapter 3.3.1, MnO₂ or NO₃⁻ was added as the standard electron acceptor. *S. marisnigri* and *S. gotlandica* showed growth under all tested headspace O₂ contents (Fig. 40). Growth of *S. baltica* was observed at 0%, 1% and 4% O₂, but in contrast to *S. marisnigri* and *S. gotlandica*, no growth could be detected at 21% O₂. Elevated O₂ content in the headspace had no effect on doubling time and growth rate of *S. marisnigri*, which were overall very low in this experiment (24 to 29 h and 0.72 to 0.59 d⁻¹, respectively) with high variation (Tab. 23). Low headspace O₂ contents of 0% and 1% had no effect on the doubling time of *S. baltica* (12

h ± 0 and 12 h ± 2, respectively) but a 4% O₂ content reduced growth to doubling times of 16 h ± 5. A low O₂ content had a positive effect on growth of *S. gotlandica*.

S. gotlandica grew faster with an O₂ content of 1% compared to 0%, 4% and 21% resulting in doubling times of 12 h ± 0 compared to 17 to 20 h, respectively. The growth yield of *S. marisnigri* in the presence of all tested headspace O₂ contents was higher than in the 0% treatment. Concentration of dissolved O₂ was decreasing to sterile control bottles when growth was detectable (Tab. 24). No change in dissolved O₂ concentration was observed in the 21% headspace O₂ treatment with *S. baltica*, where no growth was detectable. Leftover concentrations of NO₃⁻ were higher after growth of *S. gotlandica* when O₂ was present in the bottle headspace (Tab.24), indicating that O₂ was utilized concurrent with NO₃⁻. About 4 mM

Figure 40: Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* inoculated with varying oxygen contents in the headspace and the addition of either MnO_2 or NO_3^- .

	1	-18	2	3.0	0.6
	0	-2	0	1.8	0.4

NO_3^- out of approximately 10 mM NO_3^- added initially remained in the parallel with the highest headspace O_2 content of 21% compared to 1.8 mM NO_3^- when no O_2 was introduced into the headspace (Tab. 24). Nitrite (NO_2^-) was not detectable ($< 50 \mu\text{M}$). Unfortunately, no complete growth curve was recorded for *S. baltica* and *S. gotlandica* and no conclusion towards an overall growth yield can be made.

Cell morphology of *S. marisnigri*

Cells of *S. marisnigri* (Fig 41 and 42) possess one polar flagellum (Fig. 42C, red arrows) and showed movement under phase contrast microscopy. Mn-particles are often covered with threads (Fig. 42D), but whether these threads are somehow similar to the periplasmic exten-

Figure 41: DAPI stained fluorescence images (A and B) and scanning electron micrograph (C) of *S. marisnigri*. Scale bars: A, 5 μm . B, photograph through the eyepiece of the microscope, compare size to A. C, 1 μm .

sions of the metal reducing bacterium *Shewanella oneidensis* MR-1, so called nano-wires, and if they are of bacterial origin is so far unknown. Cells contained either no, one or two polyphosphate(PolyP)- inclusions indicated by the yellow color at the cell poles (Fig. 41A and B) when stained with the DNA dye DAPI. At late stages of growth, coccoid cells appear frequently (Fig. 41B and C), especially when the electron donor is oversupplied (or the electron acceptor is limited, respectively), but whether there is a causal relation to these observations was not investigated.

Figure 42: Scanning electron micrographs of a *S. marisnigri* culture grown with MnO_2 and $\text{S}_2\text{O}_3^{2-}$. Scale bars: A and B, 5 μm . C and D, 2 μm .

Genomic potential of *S. marisnigri*

The annotated genome of *S. marisnigri* was screened for marker genes involved in carbon, nitrogen, oxygen and sulfur metabolism (Tab. 25). Genes detected by the automated annotation from RAST were marked with † and genes detected via the comparison to the genome of the closely related species *S. gotlandica* (Grote et al., 2012) were marked with *. Three marker genes for CO₂ fixation via the reverse tricarboic acid cycle (rTCA) were detected by RAST annotation as well as comparison to the annotated genome of *S. gotlandica*. Genes involved in the fixation of N₂: *nifD*, *nifK* and *nifH* were detected by RAST annotation. A *ccoNOQP* cluster involved in the reduction of O₂ was detected via RAST annotation and comparison to *S. gotlandica*. NO₃⁻ reduction via a periplasmatic nitrate reductase (Nap) was found with the gene cluster *napAGHBFLD*, but further genes encoding for NO₂⁻ reductases were not detectable. Interestingly, genes for a putative nitric oxide (NO) reductase (Nos) might be present, but no statement whether this is a functioning gene or a false annotation can be made. Sulfur oxidation is represented by a functional *sox* gene cluster (*soxXYZAB*) together with multiple copies of a sulfide:quinone oxidoreductase (*sqr*). Genes involved in the accumulation and degradation of polyphosphates by polyphosphate kinase (*ppk*) and exopolyphosphatase (*ppx*) were identified by RAST annotation.

Table 25: Presence of specific marker genes involved in carbon, nitrogen and sulfur metabolism in the genome of *S. marisnigri*. *Mapped to the genome of *S. gotlandica*. †By RAST annotation.

4 Discussion

4.1 Bacterial sulfur oxidation coupled to Mn reduction and a general view onto pelagic redoxclines with focus on the Black Sea

Since decades dark CO₂ fixation rates together with H₂S oxidation in the absence of O₂ and NO₃⁻ were observed (e.g. Taylor et al., 2001; Grote et al., 2008). Although earlier attempts to cultivate organisms with the ability to utilize MnO₂ for H₂S oxidation have failed (Jannasch et al., 1991), even in more recent literature this metabolic pathway was suggested (Taylor et al., 2001; Jost et al., 2010), but evidence was so far missing. With the isolation of *S. marisnigri* and *S. baltica*, representative species from the Black Sea and the Baltic Sea have been shown to grow with reduced sulfur compounds provided as electron donor and MnO₂ provided as electron acceptor (e.g. Fig. 15, 16 and chapter 3.3.7). Both organisms belong to the genus *Sulfurimonas*, which is globally abundant in environments with strong redox gradients, such as pelagic redoxclines, marine sediments and hydrothermal deep-sea vents (Han & Perner, 2015). *Sulfurimonas* belongs to the group of *Epsilonbacteraeota*, which is suggested to be of significant importance for biogeochemical and geological processes throughout Earth's history as primary colonizers by generation of organic carbon via dark CO₂ fixation and e.g. acid dissolution of limestone via biological H₂S oxidation (Campbell et al., 2006). In pelagic redoxclines of e.g. the Black Sea, the Baltic Sea or the Cariaco Trench, up to 30% of the total bacterial community is actively fixing CO₂ (Ho et al., 2004; Grote et al., 2007, 2008; Jost et al., 2010). Among these autotrophic bacteria, *Epsilonbacteraeota* were found as the dominant group representing up to 70% of the CO₂ fixing bacteria of the Baltic Sea and up to 100% of the CO₂ fixing bacteria in the Black Sea (Grote et al., 2008). In the Baltic Sea, *Sulfurimonas* subgroup GD17 was further shown to be the dominant group within the group of *Epsilonbacteraeota* (Grote et al., 2008) and cells of the genus *Sulfurimonas* were almost exclusively representing the group of *Epsilonbacteraeota* in the Black Sea (Prof. Dr. Klaus Jürgens, pers.

communication – see also chapter 3.2.2), providing strong evidence, that *Epsilonbacteraeota* and the genus *Sulfurimonas* in particular may have a strong influence on the biogeochemistry of the respective habitat and may offer together with the results of this thesis a plausible explanation for dark CO₂ fixation rates in the absence of O₂ and NO₃⁻ (Taylor et al., 2001; Ho et al., 2004; X. Lin et al., 2006; Jost et al., 2010).

S. marisnigri oxidized H₂S and S₂O₃²⁻ to SO₄²⁻ with MnO₂ as terminal electron acceptor. The oxidation proceeded without the accumulation of S compounds with intermediate oxidation state, e.g.: S⁰, S₂O₃²⁻ or SO₃²⁻. Alike, at the bottom boundary of the suboxic zone where H₂S is consumed, no pronounced accumulation of these intermediates was observed (Jørgensen et al., 1991; Luther III et al., 1991; Glazer et al., 2006). A purely abiotic oxidation of H₂S would result in a variety of sulfur species, e.g. S⁰, S₂O₃²⁻ and SO₄²⁻ depending on the pH and the ratio of MnO₂ to H₂S (Yao & Millero, 1996; Herszage & dos Santos Afonso, 2003). For example, at near neutral pH with a MnO₂/H₂S ratio of 1, S⁰ is the important reaction product with a yield of approximately 80 to 90%. Lower MnO₂/H₂S ratios and higher pH foster S⁰ as reaction product, while higher MnO₂/H₂S ratios and lower pH result in increasing quota of SO₄²⁻ and to a minor extent S₂O₃²⁻ (Yao & Millero, 1996; Herszage & dos Santos Afonso, 2003). In the Black Sea, the MnO₂/H₂S ratio is about 0.04 (Schulz-Vogt et al., 2019) at a pH of 7 to 8, favoring S⁰ as the product of abiotic oxidation of H₂S. Thus, the missing accumulation of sulfur intermediates in the Black Sea suboxic zone strongly suggests a biological mode of H₂S oxidation.

H₂S oxidation rates appeared to be of significant importance for the retention of H₂S at the bottom boundary of the suboxic zone (Fig. 21) and the formation of linear concentration profiles of H₂S measured in-situ [e.g. Schulz-Vogt et al. (2019)]. A lower reaction rate coefficient based on chemical oxidation of H₂S by MnO₂ (k_{chem}) calculated after Yao & Millero (1993) with a constant MnO₂ concentration of 10 nM (Schulz-Vogt et al., 2019) resulted in the collapse of the suboxic zone. Apparently, a local high H₂S oxidation rate is essential for

the formation and maintenance of the suboxic zone and H₂S concentration profile of the Black Sea which coincides with a local maximum in the transcription of *sqr* by *Sulfurimonas* spp. (Prof. Dr. Klaus Jürgens, personal communication). Next to the absence of sulfur intermediates, this also strongly suggests a biological mode of H₂S oxidation at the chemocline of the Black Sea.

The H₂S oxidation rates per cell which were estimated in the present study are based on the difference in the H₂S oxidation rate before and after treatment with either sodium azide ($k_{\text{bio(A)}}$) or heat pasteurization ($k_{\text{bio(P)}}$). While heat pasteurization reduced the overall reaction rate to the chemical background, sodium azide had an inhibitory effect of approximately 25% (Tab. 21). Also Myers and Nealson (1988) reported a partial inhibition of organotrophic Mn reduction for *Shewanella oneidensis* MR-1 with sodium azide of 37%. Therefore, $k_{\text{bio(P)}}$ can be assumed as the more realistic value for H₂S oxidation by *S. marisnigri* than $k_{\text{bio(A)}}$.

Together with the cell abundance of *Epsilonbacteraeota* in Black Sea waters, which were represented by over 90% *Sulfurimonas* spp. (Prof. Dr. Klaus Jürgens, pers. communication), estimated H₂S oxidation rates by *S. marisnigri* are high enough to counterbalance H₂S fluxes from the euxinic bottom waters (Fig. 21). In-situ H₂S oxidation rates measured by Jørgensen et al. (1991) were compared to rates estimated with *S. marisnigri* in lab experiments in Tab. 26. Jørgensen et al. (1991) reported an abrupt decrease in H₂S oxidation below the Black Sea chemocline. Likewise, depth profile of the expression of the *sqr*, which is almost exclusively affiliated to species of the genus *Sulfurimonas*, shows a sharp drop to 0 below the chemocline (Prof. Dr. Klaus Jürgens, personal communication). Assuming a cellular abundance of 4×10^7 cells L⁻¹, reflecting the abundance of *Epsilonbacteraeota* (Fig. 21), a potential H₂S oxidation rate by *Sulfurimonas* can be calculated at ambient concentrations of H₂S, which are in the same order of magnitude and comparable to in-situ H₂S oxidation rates estimated by Jørgensen et al. (1991) shown in Tab. 26.

Table 26: H₂S oxidation rates estimated in pure culture with *S. marisnigri* compared to in situ H₂S oxidation rates measured by Jørgensen et al. (1991).

C _{H₂S} (μM)	Cells (L ⁻¹)	H ₂ S _{ox} (μM s ⁻¹) $k_{\text{bioA}}/k_{\text{bioP}}$	H ₂ S _{ox} (μM s ⁻¹) Jørgensen et al. (1991)
2.5	~ 4 x 10 ⁷	3.16 x 10 ⁻⁶ / 1.05 x 10 ⁻⁵	~ 1.3 x 10 ⁻⁵
4	~ 4 x 10 ⁷	5.05 x 10 ⁻⁶ / 1.68 x 10 ⁻⁵	~ 3.5 x 10 ⁻⁵
8.5	~ 4 x 10 ⁷	1.07 x 10 ⁻⁵ / 3.57 x 10 ⁻⁵	~ 6.6 x 10 ⁻⁵

H₂S oxidation rates can be transformed and compared to Mn reduction rates measured in the Black Sea by assuming that 4 mole of MnO₂ can be reduced to Mn²⁺ for every mole H₂S oxidized to SO₄²⁻ according to Tab. 2. Lewis & Landing (1991) modeled Mn reduction rates at the lower boundary of the Black Sea suboxic zone, which were 3.7 x 10⁻⁸ μM s⁻¹ and 1.2 x 10⁻⁸ μM s⁻¹ at two different stations. Assuming a cellular abundance of 4 x 10⁷ cells L⁻¹, H₂S concentrations as low as 7 nM and 2 nM based on $k_{\text{bio(A)}} \cdot 4$ and 2 nM and 0.7 nM based on $k_{\text{bio(P)}} \cdot 4$ would be sufficient to account for the modeled Mn reduction rates, respectively.

Based on the assumption that the suboxic zone is a tens of meter thick layer that shuttles oxidation potential from the oxic surface water layer to the sulfidic bottom water by e.g. a Mn cycle (Burdige & Nealson, 1986; Lewis & Landing, 1991; Yao & Millero, 1993; Dellwig et al., 2010), fluxes of O₂ into the suboxic zone from surface waters and fluxes of H₂S from euxinic waters have to be stoichiometric to result in a stable formation of the suboxic zone. Fluxes of O₂ from oxygenated surface waters into the suboxic zone and fluxes of H₂S from the euxinic water body into the suboxic zone were calculated based on Fick's first law of diffusion (Eq. 4.22),

$$J = -D \frac{\Delta c}{\Delta x} \quad 4.22$$

with J as the flux, D as the diapycnal diffusivity coefficient derived from (Gregg & Yakushev, 2005), c as concentration of the respective compound and x as distance (depth). With data collected by Schulz-Vogt et al. (2019), an O₂ flux of 1.66 x 10⁻⁶ mmol O₂ m⁻² s⁻¹ and a H₂S flux of 1.34 x 10⁻⁶ mmol H₂S m⁻² s⁻¹ was calculated (Tab. 27). Assuming a reduction of O₂ to H₂O and an oxidation of H₂S to SO₄²⁻, 4 moles of e⁻ are transferred per mole O₂ reduced and 8 e⁻

are transferred per mole of H₂S oxidized (Tab. 28). The fluxes of O₂ and H₂S can therefore be multiplied by 4 and 8 to calculate the flux of electron accepting potential (J_{e- acc.}) and electron donating potential (J_{e- don.}) into the suboxic zone. The accepting flux derived from the O₂ flux is 6.64 x 10⁻⁶ mmol electrons m⁻² s⁻¹ and the donating flux derived from H₂S flux is 1.07 x 10⁻⁵ mmol electrons m⁻² s⁻¹. The bottom boundary of the suboxic zone is thereby missing 4.08 x 10⁻⁶ mmol electron accepting potential m⁻² s⁻¹ or 4.08 nmol m⁻² s⁻¹ of oxidation potential to balance the net flux of electrons across the suboxic zone (Tab. 27, bold).

Potentially, riverine input of MnO₂ could be an external source of electron accepting potential which may explain this discrepancy. To evaluate the magnitude of a potential impact on the water column geochemistry of riverine discharge, an example calculation will be carried out with the Danube River, which represents 50 – 71% of the total riverine input into the Black Sea (Özsoy & Ünlüata, 1997; Jaoshvili, 2002; Murray & Yakushev, 2006). The Danube River discharges 190 – 250 km³ yr⁻¹ \triangleq 6025 – 7927 m³ s⁻¹ of water into the Black Sea (Bondar, 1991; Jaoshvili, 2002; Murray & Yakushev, 2006), which contains 20 mg L⁻¹ sus-

Table 27: Data used for the calculation of electron fluxes across the suboxic zone of the Black Sea

Term	Value
$\Delta c/\Delta x$ O ₂ [†]	0.83 mmol m ⁻³ m ⁻¹
$\Delta c/\Delta x$ H ₂ S [†]	0.67 mmol m ⁻³ m ⁻¹

MnO ₂	Mn ²⁺	+ 2 e ⁻

pended matter (Guieu et al., 1998). In the suspended matter Mn contents of 1704 ppm are reported (Guieu et al., 1998), which equates to $620 \mu\text{mol Mn m}^{-3}$. The annual input of Mn into the Black Sea with a surface area of $4.2 \times 10^5 \text{ km}^2$ (Özsoy & Ünlüata, 1997) from the Danube is $6.47 \times 10^3 - 8.51 \times 10^3 \text{ t Mn}$, which equates to $8.9 \times 10^{-3} - 11.7 \times 10^{-3} \text{ nmol Mn m}^{-2} \text{ s}^{-1}$. Assuming that each MnO_2 can accept two electrons (Tab. 28), $17.8 \times 10^{-3} - 23.4 \times 10^{-3} \text{ nmol electrons m}^{-2} \text{ s}^{-1}$ can be accepted by the flux of Mn, only providing 0.44 – 0.57% of the calculated need of $4.08 \text{ nmol m}^{-2} \text{ s}^{-1}$. The real fluxes might be even smaller because shelf areas may influence the amount of Mn reaching central parts of the Black Sea from the rivers and counterclockwise circulation around the deep basins will affect the dispersal of the riverine Mn, too (Oguz et al., 1993). Even though the Danube River is not the only external source of oxidative potential for the Black Sea, the overall input of Mn is likely too low to compensate the discrepancy between O_2 and H_2S fluxes into the suboxic zone.

A fraction of the electrons, donated by the H_2S flux ($J_{\text{e- don.}}$), is used by chemo-lithoautotrophic bacteria to fix CO_2 . The fixation of one mole inorganic CO_2 is accepting 4 mole e^- (Eq. 1.1). Based on the Mn(IV)/Mn(II) to $\text{S}_2\text{O}_3^{2-}/\text{SO}_4^{2-}$ ratio of 3.7 in the growth experiment with *S. marisnigri* (Fig. 15), an e^- demand of 7.5% from the bulk of electrons provided by the electron donor can be calculated which is most probably used for the reduction of CO_2 to organic C. Applying this percentage to the Black Sea and assuming a H_2S oxidation by chemo-lithoautotrophic bacteria, CO_2 fixation could account for $8.03 \times 10^{-7} \text{ mmol electron m}^{-2} \text{ s}^{-1}$ or 19.7% of the missing electron accepting budget ($J_{\text{e- don.}} - J_{\text{e- acc.}}$). From literature, values up to 20% are reported for the fixation of CO_2 by chemolithoautotrophic bacteria (Kelly, 1982), which would explain about 50% of the discrepancy between $J_{\text{e- acc.}}$ and $J_{\text{e- don.}}$. CO_2 fixation rates of up to $2.32 \times 10^{-6} \text{ mmol m}^{-3} \text{ s}^{-1}$ estimated by Jørgensen et al. (1991) or $9.26 \times 10^{-6} \text{ mmol m}^{-3} \text{ electrons accepted s}^{-1}$ may balance the excess flux of $4.08 \text{ mmol m}^{-3} \text{ s}^{-1}$ electrons from $J_{\text{e- don.}}$.

Just recently, Schulz-Vogt et al. (2019) showed that large magnetotactic bacteria are moving through the complete suboxic zone displacing phosphate vertically by internal storage of polyP. The authors suggested that these bacteria might store NO_3^- internally in vacuoles for the oxidation of H_2S at the lower boundary of the suboxic zone. To account for the missing $4.08 \times 10^{-6} \text{ mmol e}^-_{\text{acc}} \text{ m}^{-2} \text{ s}^{-1}$, $8.16 \times 10^{-7} \text{ mmol NO}_3^- \text{ m}^{-2} \text{ s}^{-1}$ would have to be displaced by large magnetotactic bacteria. Because the concentration profile of NO_3^- is approaching zero together with the concentration profile of NH_4^+ and turned into N_2 by anaerobic ammonium oxidation (anammox) [Kuypers et al. (2003)], it may be assumed that NO_3^- is completely exhausted due to the reduction to NO_2^- and subsequently to N_2 by anammox, but Kuypers et al. (2003) showed that the flux of NO_3^- is $2 \mu\text{mol m}^{-2} \text{ h}^{-1}$ larger than the flux of NH_4^+ . The remaining $2 \mu\text{mol NO}_3^- \text{ m}^{-2} \text{ h}^{-1}$ are equal to $5.56 \text{ mmol NO}_3^- \text{ m}^{-2} \text{ s}^{-1}$ which could explain 68% of the missing electron accepting potential at the chemocline. No loss of NO_3^- for the degradation of organic matter can be expected, because no heterotrophic denitrification was detectable in the depth of NO_3^- removal (Jensen et al., 2008).

In summary, concentration gradients and the resulting fluxes of O_2 and H_2S directly above and below the suboxic zone are unbalanced. External input of oxidized compounds, e.g. by riverine input, may not have a big impact on the stoichiometry of the suboxic zone. Internal sinks for e^- might be the fixation of CO_2 by chemolithoautotrophic bacteria and the displacement of NO_3^- by large magnetotactic bacteria. However the mechanism of intracellular transport of NO_3^- by large magnetotactic bacteria remains to be proven.

4.2 Mechanism of MnO₂ reduction and potential implications for Mn(Ca)CO₃ authigenesis

4.2.1 Biological MnO₂ reduction and competition with an abiotic reaction

The reduction of particulate electron acceptors like Mn or Fe is a challenging task for bacteria. Electrons from an electron donor have to be transferred from the cytoplasmic membrane to the cell outside onto the particulate electron acceptor. On the basis of microscopic inspection and SIMS analysis, it appeared that *S. marisnigri* is depending on physical contact with the Mn particle surface (Fig. 12, 13 and 14). This is in agreement with considerations of Canfield et al. (2005), because in contrast to Fe oxides MnO₂ is practically insoluble at near neutral pH and a direct electron transfer should be necessary for the reduction. Physical contact, however, can be either direct via the cell surface (Myers & Myers, 2003), periplasmatic extensions of the outer membrane (El-Naggar et al., 2010; Pirbadian et al., 2014), conductive pili (Bond & Lovley, 2003) or the transfer of e⁻ with molecules e.g. flavine, quinone or humic acids (Nevin & Lovley, 2002; Marsili et al., 2008; Canstein et al., 2008 - Fe). Whether *S. marisnigri* transfers electrons with the above mentioned systems or in a different way remains to be elucidated.

Biological oxidation of H₂S in the presence of MnO₂ has to face similar difficulties as the biological oxidation of H₂S with O₂ as terminal electron acceptor. In contrast to e.g. the oxidation of H₂S with NO₃⁻, H₂S reacts abiotically with O₂ and MnO₂ (Chen & Morris, 1972; Burdige & Nealson, 1986; Yao & Millero, 1993) which is a loss of potential energy for the organism. Strategies to minimize the loss of potential energy to a chemical reaction are e.g. the spatial separation of the oxidation and the reduction reaction or to compete with the chemical reaction by a faster biological reaction rate. Species of the *Desulfobulbaceae* form long filaments with a conductive outer envelope at sedimentary redoxclines and perform the oxidation of H₂S and the reduction of O₂ at the respective poles of the filament and shuttle the electrons over centimeter wide distances (Nielsen & Risgaard-Petersen, 2014). As pointed out

in the introduction, local high reaction rates by *Beggiatoa* result in low local concentrations or even depletion of the reactants (Jørgensen & Revsbech, 1983). As a further advantage, this local depletion increases the concentration gradient and increases the net flux of the reactants and thus the input of potential energy.

The same may apply for the biological oxidation of H_2S with MnO_2 (Fig. 43). The chemical reaction rate of H_2S with MnO_2 follows a chemical reaction of second order and depends on the concentration of H_2S and the surface area of MnO_2 (Yao & Millero, 1993). Low reactant concentrations result in low reaction rates. Because H_2S needs to have contact to the MnO_2 particle surface to react chemically, the visible attachment and proliferation of *S. marisnigri* on the MnO_2 particle surface (Fig. 12) might hamper the chemical reaction by blocking reactive surface sites of the MnO_2 particle [like *Geobacter sulfurreducens* (Fig. 5 in Bond & Lovley, (2003))]. Additionally, active biological H_2S oxidation keeps the H_2S concentration at the particle surface low, thereby suppressing the chemical reaction. The chemical two e^- transfer oxidation of H_2S to S^0 with MnO_2 (Tab. 2, Eq. 3.18) is surface controlled, pH depend and the reactivity decreases with increasing pH (Yao & Millero, 1993, 1996; Luther III, 2010). As shown in Tab. 2, Eq. 3.17, 3.18 and Fig. 15D, the pH increases due to MnO_2 reduction with reduced sulfur compounds, which should also inhibit the competing chemical reaction of H_2S and MnO_2 .

4.2.2 Theoretical implications for the authigenesis of $\text{Mn}(\text{Ca})\text{CO}_3$

The activity of *S. marisnigri* at the particle surface may also offer a plausible explanation for the precipitation of $\text{Mn}(\text{Ca})\text{CO}_3$, which was observed at MnO_2 particles (Fig. 13 and 14). The precipitation of $\text{Mn}(\text{Ca})\text{CO}_3$ is an interesting finding, because Ca-rich MnCO_3 layers occur frequently in geological records (Neumann et al., 2002; Dellwig et al., 2018, 2019; Häusler et al., 2018; Hermans et al., 2019), but the mechanism of formation is still under debate. Chemical studies of Middelburg et al. (1987) suggested a precipitation of Ca-rich MnCO_3 when dis-

solved Mn reaches supersaturation, but oversaturated porewater profiles did not show precipitation (Carman & Rahm, 1997; Lenz et al., 2015; Dellwig et al., 2018; Häusler et al., 2018). Experiments of Mucci (1988) and Böttcher (1998) showed that precipitation is depending on the kinetic of precipitation and Böttcher (1998) suggested a putative microbial involvement in the precipitation process. Böttcher (1998) was able to chemically precipitate the complete solid solution series of $\text{Mn}_x\text{Ca}_{1-x}\text{CO}_3$ with $x = 0.25$ to 0.75 chemically. In contrast to this, Ca-rich MnCO_3 found in the Baltic Sea sediments shows a distinct Ca content analogue to the $\text{Mn}(\text{Ca})\text{CO}_3$ precipitated in this study (Fig. 14 and 15, Patricia Roeser, personal communication).

In the Baltic Sea, Ca-rich MnCO_3 layers are often observed concurrent with major baltic inflow (MBI) events (Häusler et al., 2018). MBI's are intrusions of dense, oxygen rich waters from the North Sea into the anoxic and often euxinic basins of the Baltic Sea (Matthäus & Franck, 1992). Dissolved Mn^{2+} in the euxinic waters is oxidized and transported to the sediment surface as MnO_2 where it accumulates in the deeper basins (Sulu-gambari et al., 2017; Häusler et al., 2018; Hermans et al., 2019). Hermans et al. (2019) showed the formation of Ca-rich MnCO_3 at the sediment surface in June 2016 after a MBI at the end of 2015 to beginning of 2016. Ca-rich MnCO_3 precipitation was also observed in the Baltic Sea sediments near the surface and the difference in $\delta^{18}\text{O}$ between MnCO_3 precipitates and porewaters emphasized a role of microbial MnO_2 reduction during Ca-rich MnCO_3 authigenesis (Neumann et al., 2002). High MnO_2 content together with ongoing sulfate reduction resulting in H_2S fluxes from deeper sediment layers are analogue to the culturing conditions of *S. marisnigri* shown in Fig. 16, where $\text{Mn}(\text{Ca})\text{CO}_3$ precipitated as indicated by an increasing Ca content in the particulate phase.

In the experiments shown in the present work with precipitation of $\text{Mn}(\text{Ca})\text{CO}_3$ (e.g. Fig. 14 and 15), precipitation might be fostered by the high alkalinity of approximately 30 mM due to pH buffering with HCO_3^- and pH adjustment with N_2 gas with 10-30% CO_2 . However, also in

culturing approaches with pH buffering based on HEPES and pH adjustment with H_2SO_4 (Fig. 39) a color change implying $\text{Mn}(\text{Ca})\text{CO}_3$ precipitation was observed. This may indicate that the artificial high alkalinity might not be the major factor controlling $\text{Mn}(\text{Ca})\text{CO}_3$ precipitation in the presented experiments. In theory, concentration of Mn^{2+} and CO_3^{2-} should be the major factor controlling the precipitation of $\text{Mn}(\text{Ca})\text{CO}_3$. Hypothetical implications of bacterial proliferation on MnO_2 particles which may result in the precipitation of $\text{Mn}(\text{Ca})\text{CO}_3$ are visualized in Fig. 43. The reduction of MnO_2 and oxidation of H_2S is increasing the con-

Figure 43: Hypothetical implications of bacterial proliferation on MnO_2 particles. MnO_2 dependent H_2S oxidation leads to the production of dissolved Mn^{2+} , increasing pH and low concentrations of H_2S near the particle surface. Thereby, the chemical oxidation of H_2S is suppressed and the flux of H_2S is increased due to a steeper concentration gradient. The increase in pH in the microenvironment of the Mn particle stimulates the precipitation of Mn-carbonate due to the higher proportion of CO_3^{2-} at higher pH together with high concentrations of Mn^{2+} .

centration of Mn^{2+} at the particle surface and the pH according to Eq. 3.17. According to Glasby & Schulz (1999), MnCO_3 is the stable form of Mn(II) under seawater conditions with a pH of 9 to 12. Increased pH shifts Eq. 4.23 to the right,

which increases the portion of free CO_3^{2-} ions and stimulates the formation of carbonate precipitates (Brown et al., 1989). This may be a plausible explanation for observed Ca-rich MnCO_3 precipitates in Baltic Sea sediments after a major Baltic inflow event by altering the micro-environment around a MnO_2 particle.

4.3 Ecological potential of *S. marisnigri*, *S. baltica* and *S. gotlandica* in comparison to other species of the genus *Sulfurimonas*

4.3.1 Electron acceptors

Oxygen

S. marisnigri, *S. baltica* and *S. gotlandica* showed growth with O_2 as electron acceptor under the described culturing conditions (Fig. 22). This is in contrast to Labrenz et al. (2013), who stated, that *S. gotlandica* is unable to utilize O_2 as electron acceptor. So far, all other isolated strains of the genus *Sulfurimonas*: *S. denitrificans*, *S. hongkongensis*, *S. autotrophica* and *S. paralvinellae* were reported to utilize O_2 as terminal electron acceptor (See references in Tab. 29). Han & Perner (2015) argued that the absence of growth with O_2 as electron acceptor reported by Labrenz et al. (2013) may not have been detected with the respective growth experiments. Labrenz et al. (2013) also stated that the growth rates under the tested conditions might just have been too low to be detectable. The observed growth of *S. gotlandica* in this work is supported by the decreasing O_2 concentrations in the medium (Fig. 22 and Tab. 22). Further, NO_3^- seemed to be substituted by O_2 as electron acceptor by *S. gotlandica* when cultivated with NO_3^- and O_2 to test for O_2 tolerance (Fig. 40, Tab. 24). Leftover concentrations of NO_3^- were higher at the end of growth when higher O_2 concentrations were present in the

bottles (Tab. 24). This is in agreement with the genetic potential of *S. gotlandica* and all of the so far sequenced *Sulfurimonas* species: *S. denitrificans*, *S. hongkongensis*, *S. autotrophica*, *S. gotlandica* and *S. marisnigri*. All genomes of these strains contain a *ccoNOQP* operon. The *ccoNOQP* operon encodes for a cbb3-type cytochrome c oxidase (Han & Perner, 2015) and is responsible for the reduction of O₂ to H₂O by transferring e⁻ from cytochrome c to O₂, thereby generating a proton gradient (Pitcher & Watmough, 2004).

Denitrification in the presence of O₂ is a subject of ongoing discussion. Marchant et al. (2017) reported denitrification from intertidal flats in the Wadden Sea at O₂ concentration above 100 µM. In contrast to that, O₂ concentrations as low as 2 µM were shown to inhibit denitrification in O₂ minimum zones (Dalsgaard et al., 2014), but did also show that the tested O₂ concentrations had little to no effect on the expression of *narG*, catalyzing NO₃⁻ reduction, but expression of *norB*, catalyzing nitric oxide reduction, was strongly affected. Therefore, decreasing concentrations of NO₃⁻ in the presence of approximately 200 µM O₂ with *S. gotlandica* (Fig. 40 and Tab. 24) may not have resulted in the formation of N₂ but intermediates, which were not investigated. This finding is worth to be tested in a separate experiment in pure culture with *S. gotlandica*.

For *S. marisnigri* and *S. baltica*, no concentrations of MnO₂ or total dissolved Mn in the presence of O₂ were measured. Thus, no reduction of MnO₂ in the presence of O₂ could be demonstrated directly. The growth yield of *S. marisnigri* after 11 days with 21% O₂ and 4% O₂ headspace content was comparable (Fig. 40). Because the difference in the dissolved O₂ concentration was larger in the 21% O₂ treatment (Tab. 24), the comparable growth yield may indicate the reduction of MnO₂ in the presence of 4% O₂ in the bottle headspace, which does not exclude MnO₂ reduction by *S. marisnigri* in the presence of higher O₂ concentrations.

Nitrate

S. marisnigri, *S. baltica* and *S. gotlandica* showed growth with NO₃⁻ as terminal electron acceptor but the growth yield differed strongly (Fig. 23). *S. marisnigri* reduced NO₃⁻ to NO₂⁻

and not further to N_2 as it is described for *S. gotlandica* (Labrenz et al., 2013), which is probably the reason for the lower growth yield (Fig. 23). *S. gotlandica* produced overpressure due to N_2 formation while growing. No overpressure was produced by *S. marisnigri* and *S. baltica* and the growth yields of these strains was comparable (Fig. 23). Thus it can be speculated that *S. baltica* reduced NO_3^- to NO_2^- like *S. marisnigri*, even though it was not investigated for *S. baltica*. This is supported by the absence of growth, when *S. marisnigri* and *S. baltica* are cultivated with NO_2^- as terminal electron acceptor (Fig. 25). This is in accordance with the genome of *S. marisnigri*. A periplasmatic nitrate reductase (Nap) was detected (Tab. 25) responsible for the reduction of NO_3^- to NO_2^- , but in contrast to the genome of *S. gotlandica* (Grote et al., 2012), no genes for the dissimilatory reduction of NO_2^- (*nir*) have been found. This is supporting the observed results in pure culture growth experiments. Interestingly, a nitric oxide reductase (Nor) is present in the genome of *S. marisnigri*, but whether this gene is functional remains to be tested in growth experiments.

Metal oxides

The test for growth on Fe and Mn oxides was difficult, because all strains showed growth with O_2 as terminal electron acceptor (Fig. 22) and cultivation was performed without reducing agents and redox indicators, because preliminary test showed inhibiting effects of these compounds on growth of *S. marisnigri*. Due to the lack of a reducing agent, O_2 contaminations of $< 10 \mu\text{M}$ are likely present in all cultivation attempts. Therefore, as described in the results part, visualization with SEM and DAPI staining epifluorescence microscopy was performed to look for cell attachment of all three strains to Fe and Mn oxide particles. Attachment of *S. marisnigri* and *S. baltica* with MnO_2 as it is shown in Fig. 12, 13 and 14 was not observed when Fe oxides were provided as electron acceptor. No attachment of *S. gotlandica* with either Fe or Mn oxides was observed. Because the essential genes involved in the reduction of MnO_2 by *S. marisnigri* and *S. baltica* are currently unknown, this cannot be supported by the presence or absence of specific genes in the genome of *S. gotlandica*. The ability to re-

duce MnO_2 together with the inability to reduce Fe oxides by *S. marisnigri* and *S. baltica* is an important finding because it differs from the so far described organisms capable of organotrophic metal oxide reduction, which typically grow on different particulate electron acceptors like Fe, Cr, U or Tc (Lovley, 1991; Marshall et al., 2008; H. Lin et al., 2012). For *Shewanella oneidensis* MR-1, an organotrophic Mn reducing bacterium able to reduce Mn and Fe, it was shown, that different protein components are active for the reduction of either Fe or Mn (H. Lin et al., 2012). Thus, the inability for Fe reduction might just be a result of gene loss due to repeated cultivation with solely Mn. Nonetheless, similar findings were reported from anoxic sediments. SO_4^{2-} was formed in anoxic sediment slurries when MnO_2 was added, apparently based on biological activity, which could not be induced by the addition of Fe oxides (Aller & Rude, 1988; G. M. King, 1990). This may indicate a biological metabolism based on MnO_2 reduction without the ability to reduce Fe oxides. Interestingly, the authors of the respective works also reported the formation of Ca-rich MnCO_3 .

4.3.2 Disproportionation

Whether disproportionation of S^0 and $\text{S}_2\text{O}_3^{2-}$ by *S. marisnigri*, *S. baltica* and *S. gotlandica* can support slow growth is difficult, as low amounts of O_2 contaminations could not be completely avoided, as described for metal oxide reduction. Nevertheless, in comparison with the well described disproportioning bacteria *Desulfocapsa sulfoexigens* (Finster et al., 1998), several differences appeared. *D. sulfoexigens* produced millimolar concentrations of H_2S with $\text{S}_2\text{O}_3^{2-}$ or S^0 as the sole energy source in the absence of Fe oxides, which are shown to oxidize H_2S chemically and precipitate as FeS and FeS_2 when they are provided (Finster et al., 1998). A production of millimolar concentrations of H_2S by *Sulfurimonas* would eliminate micromolar concentrations of O_2 and result in free H_2S , which would be detectable by H_2S microsensors and smell. This was not the case and even with higher cell numbers after an exponential growth phase exceeding 10^7 cells mL^{-1} (Fig. 33) $\text{S}_2\text{O}_3^{2-}$ concentrations remained constant.

Finally, *S. marisnigri* showed growth with $\text{S}_2\text{O}_3^{2-}$ as electron donor and NO_3^- as electron acceptor (Fig. 23 and 24). Growth was concurrent with the stoichiometric reduction of NO_3^- to NO_2^- , which cannot be attributed to $\text{S}_2\text{O}_3^{2-}$ disproportionation, because NO_3^- would not react chemically with H_2S as it might proceed in the presence of O_2 and MnO_2 .

4.3.3 Electron donors

Sulfur oxidation

The ability to oxidize reduced sulfur compounds of *S. marisnigri*, *S. baltica* and *S. gotlandica* has been shown. *S. gotlandica* showed growth with S^0 , $\text{S}_2\text{O}_3^{2-}$ and SO_3^{2-} (e.g. Fig. 23, 27 and 28) and *S. marisnigri* and *S. baltica* with H_2S , S^0 and $\text{S}_2\text{O}_3^{2-}$ (e.g. Fig. 17, 23, 27 and 37). Growth of *S. gotlandica* on H_2S is well known and has therefore not been tested in this study (Grote et al., 2012; Labrenz et al., 2013). *S. marisnigri* and *S. baltica* were unable to grow on SO_3^{2-} . The lack of the sulfite dehydrogenase (Sor) in the genome of *S. marisnigri*, encoded by *sorA* and *sorB*, may be responsible for the observed result (Fig. 28 and Tab. 29). A similar lack of metabolic potential has been reported for *S. denitrificans*, which also lacks the genes *sorA* and *sorB* and did not grow with SO_3^{2-} as electron donor (Timmer-ten Hoor, 1981; Sievert et al., 2008). SO_4^{2-} was the terminal end product of S oxidation by *S. marisnigri* in this study. Complete oxidation to SO_4^{2-} was already shown for *S. gotlandica* (Grote et al., 2012; Labrenz et al., 2013). Terminal oxidation product of H_2S , S^0 and $\text{S}_2\text{O}_3^{2-}$ of *S. baltica* was not investigated, but it can be presumed to be SO_4^{2-} based on the growth yields in comparison to *S. marisnigri* and *S. gotlandica*.

In the genome of *S. marisnigri* and all so far sequenced *Sulfurimonas* species a *soxXYZAB* cluster, which is the basic configuration for the oxidation of reduced sulfur to SO_4^{2-} with a *sox*-cluster (Frigaard & Dahl, 2008) is present (see references in Tab 29). It is suggested, that residues of short chain polysulfides enter the *sox* system bound to SoxYZ and are oxidized to SO_4^{2-} in multiple steps (Frigaard & Dahl, 2008). For the phototrophic bacterium *Rhodovulum*

sulfidophilum, the sox system also seems to be essential for the utilization of H₂S as electron donor (Appia-Ayme et al., 2001), but sox deficient mutants of *Allochromatium vinosum* show wild-type rates of H₂S oxidation, suggesting different pathways for H₂S oxidation (Han & Perner, 2015).

In species of the genus *Sulfurimonas*, oxidation of H₂S is most probably catalyzed by the enzyme sulfide:quinone oxidoreductase (SQR). So far all sequenced *Sulfurimonas* species contain several types of *sqr*, potentially adapted to different levels of H₂S with varying H₂S affinities (Marcia et al., 2010). It is unclear, whether all types of SQR form the same sulfur intermediates, but short chains of polysulfides (S_n²⁻) were thought to be the most likely product (Marcia et al., 2010; Han & Perner, 2015). Unlike hypothesized earlier (Steudel, 1996), the formation of S_n²⁻ is considered to be a product of biological H₂S oxidation rather than the product of the abiotical reaction of H₂S and S⁰ (Frigaard & Dahl, 2008), and has been reported for *Sulfurimonas* sp. in cultures (Han & Perner, 2015). S_n²⁻ can enter the Sox pathway as described earlier (Frigaard & Dahl, 2008).

Next to a functional sox-operon (*soxXYZAB*), *S. gotlandica* also contains *soxCD* (Grote et al., 2012), which was not found in the genome of *S. marisnigri*. The absence of *soxCD* in *Paracoccus pantotrophus* resulted in the decreased yield of just two electrons when S₂O₃²⁻ was provided as electron donor in contrast to an eight e⁻ yield when *soxCD* was present (Friedrich et al., 2000, 2005). It is not stated whether these six electrons are used for the reduction of the respective electron acceptor without energy generation for cell metabolism or not. This could explain the difference in the growth yield between *S. gotlandica* and *S. marisnigri* (e.g. Fig. 26, positive controls), which will be demonstrated with a short calculation. The strains were cultivated as positive controls in the experiment to test for the assimilation of organic C with S₂O₃²⁻ and MnO₂ for *S. marisnigri* and NO₃⁻ for *S. gotlandica* (Fig. 36). Because MnO₂ was limited in cultivation of *S. marisnigri* with S₂O₃²⁻ and S₂O₃²⁻ was limited in cultivation of *S. gotlandica* with NO₃⁻, the respective limiting compound concentration was

chosen for the following calculation. 20 mM of electrons can be accepted by 10 mM of MnO_2 provided as electron acceptor for *S. marisnigri*. With a total yield of 1.7×10^{10} cells L^{-1} , 8.5×10^8 cells per millimol accepted e^- were generated. For *S. gotlandica*, 32 mM of e^- can be donated by the 4 mM $\text{S}_2\text{O}_3^{2-}$ provided. With a total yield of 1×10^{11} cells L^{-1} , 3.13×10^9 cells per millimol donated e^- are generated. Dividing the 3.13×10^9 by 8.5×10^8 gives a factor of 3.68, which may reflect the loss of electrons due to the lack of *soxCD* as shown by Friedrich et al. (2000) for *P. pantotrophus*. This difference is not observed when S^0 instead of $\text{S}_2\text{O}_3^{2-}$ is supplied as electron donor (Fig. 27). Further, based on experiments with *S. marisnigri* and *S. baltica* on NO_3^- as electron acceptor and successive additions of H_2S (Fig. 17), 1.67×10^9 cells per millimol donated e^- from H_2S are generated by both strains, a doubled growth yield compared to cultivation with $\text{S}_2\text{O}_3^{2-}$. Cultivation of *S. marisnigri* on MnO_2 and a constant supply of H_2S via a peristaltic pump (Fig. 16) resulted in the generation of 1.92×10^9 cells per millimol e^- based on the produced concentration of SO_4^{2-} , an even higher growth yield than in cultivations with NO_3^- .

4.3.4 Organic carbon oxidation, fermentation and sulfate reduction

The reduction of MnO_2 or NO_3^- by the utilization of organic carbon was not observed or far less important than inorganic electron donors, which results in an uncertain evaluation of this electron donor. Studies focusing on the consumption of educts and production of the metabolites would be necessary to provide evidence regarding organotrophic Mn reduction or denitrification under these culturing conditions. Further, pyruvate, amino acids and yeast extracts might also be worth to be tested as they can be utilized by *S. gotlandica* as shown by Labrenz et al. (2013). As pointed out before, dynamics of the metabolites would need to be recorded along with cell growth to address a potential activity with fermentation or sulfate reduction by *S. marisnigri*, *S. baltica* and *S. gotlandica*. Sulfate reduction seems unlikely, because *dsr* genes are not present in the genome of *S. marisnigri* and *S. gotlandica*.

4.3.5 Assimilatory metabolism

N₂ fixation

One of the most interesting findings is the ability of *S. marisnigri* and *S. baltica* to grow without the addition of NH₄⁺ as N-source, apparently fixing molecular N₂. This has so far not been reported for the genus *Sulfurimonas*, but it is supported by the presence of genes encoding for nitrogen fixation (*nifUBTHQXEZN*) and by genes encoding for a Mo-Fe nitrogenase α - and β -chain (peg. 2006 and 2005, respectively) which are orthologue to *nifK* and *nifD*, which form the reaction center for N₂- fixation together with *nifH* (Mus et al., 2018). Compared to the respective positive controls (Fig. 35, black), growth was slower and the overall growth yield might be interpreted as lower, which could be explained by the high energy demand to break up the N \equiv N covalent bonds for the assimilation of molecular N (Havelka et al., 1982).

It is arguable whether this complex is used for the assimilation of nitrogen, because NH₄⁺ is present in micromolar concentrations at the bottom boundary of the Black Sea suboxic zone, where *S. marisnigri* was isolated from and N₂ fixation is a highly energy demanding process.

CO₂ fixation

All tested *Sulfurimonas* strains are able to fix CO₂. Autotrophic CO₂ fixation by members of the *Epsilonbacteraeota* (Hügler et al., 2005) and the genus *Sulfurimonas* is done via the reductive tricarboxylic acid cycle (rTCA). Key enzymes for the rTCA are 2-oxoglutarate:ferredoxin oxidoreductase (*oor*), pyruvate:ferredoxin oxidoreductase (*por*) and ATP-dependent citrate lyase (*acly*) (Aoshima, 2007), which are found in all sequenced *Sulfurimonas* genomes (See references in Tab. 29) and were also detected in *S. marisnigri* (Tab. 25).

Polyphosphate

Polyphosphate is a storage molecule linking phosphate residues with energy-rich phosphorane-hydride bonds. Although polyP is found in every cell, the physiological function next to responsible genes for the accumulation or degradation of polyP is under debate and often

poorly understood (Kornberg et al., 1999). PolyP was observed in cells of *S. marisnigri* (Fig. 41), *S. baltica* (not shown) and *S. gotlandica* (Möller et al., 2019). Typically, two inclusions of polyP were located at the cell poles of rod shaped cells (Fig. 41), but cells with just one inclusion or without any polyP inclusions were also observed. Sometimes cells were noticeably longer and had more than two polyP inclusions, which was also reported by Lars Möller (Master thesis) for *S. gotlandica*. Next to the visible accumulation of polyP, genes involved in the formation (polyphosphate kinase, peg. 306) and degradation (exopolyphosphatase, peg. 1175) of polyP were found in the genome of *S. marisnigri*. Functions of polyP were reported to be manifold, ranging from energy (Brock & Schulz-Vogt, 2011; Möller et al., 2019) and P storage (Harold, 1962) to regulation of the cell metabolism (Kornberg et al., 1999). PolyP in *S. marisnigri* and *S. baltica* might also serve as energy storage for motility when electron donors or acceptors become limited and to survive under unfavorable conditions, as it is reported for *S. gotlandica* (Möller et al., 2019). Accumulation of polyP during high metabolic activity together with changing cell morphology when the electron donor is becoming limited might be an adaptation for small scale migration when Mn oxides are getting depleted while sinking into euxinic waters. Because the expression of polyphosphate kinases throughout the suboxic zone is most frequently done by the genus *Sulfurimonas* (Schulz-Vogt et al., 2019), polyP might have an important role for the live strategy of *Sulfurimonas* spp. in the Black Sea.

5 Conclusion and outlook

Growth of *S. marisnigri*, *S. baltica* and *S. gotlandica* was documented with the electron acceptors O_2 and NO_3^- , *S. marisnigri* and *S. baltica* showed growth also with MnO_2 . This is the first report of manganese reduction within the genus *Sulfurimonas* and the first documented manganese reducing species able to oxidize reduced sulfur species in general. No growth was observed when Fe oxides were provided as terminal electron acceptors. Growth of all three strains with O_2 was supported by decreasing dissolved O_2 concentrations and the presence of *ccoNOQP* in the genome of *S. marisnigri* and *S. gotlandica*. In contrast to the denitrifying organism *S. gotlandica*, *S. marisnigri* reduced NO_3^- to NO_2^- without further reduction to N_2 . Based on the growth yield, the absence of an overpressure at the end of the growth phase and the absence of growth with NO_2^- as electron acceptor, it is assumed, that *S. baltica* reduces NO_3^- to NO_2^- as it was shown for *S. marisnigri*. The inorganic electron donors H_2 , H_2S , S^0 and $S_2O_3^{2-}$ supported growth of *S. marisnigri*, *S. baltica* and *S. gotlandica*, whereas SO_3^{2-} only supported growth of *S. gotlandica*. This was supported by the absence of *sorA* and *sorB* in the genome of *S. marisnigri* analogous to growth experiments and the genome reported for *S. denitrificans*. For the oxidation of reduced sulfur, *soxXYZAB* and multiple copies of *sqr* were found in the genome of *S. marisnigri*. The absence of *soxCD* might explain different growth yields in comparison with *S. gotlandica* when $S_2O_3^{2-}$ was provided as electron donor, which was not detectable when H_2S or S^0 were provided instead of $S_2O_3^{2-}$.

In the present study, *S. marisnigri* and *S. gotlandica* grew autotrophically, while *S. baltica* was able to grow also with acetate, succinate and propionate. Autotrophic growth by *S. marisnigri* with the reverse tricarboxylic acid cycle was confirmed by the presence of the three marker genes 2-oxoglutarate:ferredoxin oxidoreductase, pyruvate:ferredoxin oxidoreductase and ATP-dependent citrate lyase, similar to all so far sequenced *Sulfurimonas* strains. *S. marisnigri* and *S. baltica* showed growth in the absence of NH_4^+ with N_2 as the only

N source. The ability to fix molecular N_2 was so far not reported from species of the genus *Sulfurimonas* and should be confirmed with isotopically labeled incubation experiments. Nevertheless, a set of *nif* genes including *nifD*, *nifK* and *nifH* was detected in the genome of *S. marisnigri*, supporting the finding from the cultivation experiment. No sulfate reducing activity, fermentation or respiration of organic carbon was observed. No *dsr* genes were found in the genome of *S. marisnigri*, supporting the results from cultivation experiments. Respiration of organic material is reported for *S. gotlandica* but was not observed in this study. Disproportionation of S^0 and $S_2O_3^{2-}$ could not be completely ruled out but appears unlikely. *S. marisnigri* and *S. baltica* grew from 0 °C to 25°C and 0 °C to 20 °C, respectively. Next to *S. gotlandica*, these are the only cultured psychrotolerant species of the genus *Sulfurimonas*. Growth was observed at near neutral pH with small differences between the three species. The presence of O_2 did not result in the absence of growth.

With this finding, the high abundance of *Sulfurimonas* spp. in the pelagic redoxcline of the Black Sea in the absence of O_2 , NO_3^- and light offers a plausible explanation for measured CO_2 fixation rates in the depth of H_2S removal. The described energy metabolism is potentially of general importance for the interpretation of pelagic and sediment redox environments with implications for the biogeochemical formation and maintenance, respectively. It was shown, that the oxidation rate of H_2S is a major factor for the retention of H_2S at the lower boundary of the Black Sea suboxic zone and determines the shape of the concentration profile, indicating the importance of biological H_2S oxidation for the expansion of suboxic zones with undetectable concentrations of O_2 and H_2S .

The formation of $Mn(Ca)CO_3$ in experiments with *S. marisnigri* and *S. baltica*, even though it might be fostered by artificial culturing conditions, should be investigated in more detail. Biological reduction of Mn might facilitate the formation of Mn-carbonate precipitates by influencing the ambient concentration of dissolved Mn and CO_3^{2-} by sulfur oxidation with MnO_2 and concurrent increase in pH. Interestingly, the Ca content of the $Mn(Ca)CO_3$ precipitates in

this study is analogue to precipitates found in Baltic Sea sediments. The reduction of MnO_2 by *S. marisnigri* lead to the formation of dissolved reactive Mn, putative Mn^{3+} , which is reported as an important intermediate in the pelagic and the sedimentary Mn cycle.

Finally, the change in the cell morphology of *S. marisnigri* when the electron acceptor is becoming limited, which was also reported from *S. gotlandica*, might be an important adaptation for survival in pelagic redoxclines together with polyphosphate as redox independent energy supply. A further study examining external factors such as stoichiometry of electron acceptor and donor and the influence onto polyphosphate metabolism and cell morphology might give an insight into the extraordinary live strategy of *Sulfurimonas* spp.

7 Acknowledgements

I thank **Prof. Dr. Heide Schulz-Vogt** for several years of support and supervision. An always open door, an open mind for discussion at eye level and openness for new and not always bearing fruit ideas are exceptional and not taken for granted.

I thank my thesis committee including **Prof. Dr. Heide Schulz-Vogt, Dr. Falk Pollehne, Dr. Olaf Dellwig, Dr. Kai Finster, Dr. Matthias Labrenz** and **Prof. Dr. Friedrich Widdel** for assistance and guidance throughout the time of the dissertation.

I thank the **Deutsche Forschungsgemeinschaft (DfG)** for funding the project ANAMARE (grant number SCHU1416/5-1).

I thank the **working group ‘Geomikrobiologie’** and the **working group ‘Mikrobielle Prozesse und Phosphorkreislauf’** at the IOW for several years of discussion even though I missed a lot of the meetings.

I thank **Prof. Dr. Klaus Jürgens** for the permission to use environmental data of bacterial abundances and molecular data of *Epsilonbacteraeota* and *Sulfurimonas* of the Black Sea.

I thank **Christin Laudan** for years of help and joy in- and outside the lab.

I thank **Christian Burmeister, Christian Meeske, Anne Köhler, Katja Käding, Ronny Baaske, Sascha Plewe, Bolle** and **Stefan Otto** for lab assistance and help with methodology.

I thank **Dr. Olaf Dellwig** for important contribution in the work concerning manganese analysis, general criticism and discussion.

I thank **Dr. Falk Pollehne** for helpful discussion regarding the complex biogeochemical system of the Black Sea.

I thank **Dr. Thomas Schott** for the bioinformatics procession of the genomic sequence data of *S. marisnigri* and *S. gotlandica*.

I thank **Dr. Patricia Roeser** for providing helpful comments, discussion and information regarding natural manganese-carbonate depositories.

I thank **Dr. Angela Vogts** and **Annett Grüttmüller** for Nano-SIMS analysis and help with the look@NanoSIMS tool.

I thank **Dr. Thomas Leipe** for the analysis of TIC.

I thank **Prof. Dr. Klaus Jürgens**, **Prof. Dr. Daniel Herlemann**, **Dr. Matthias Labrenz** and **Dr. Peter Holtermann** for discussion, ideas in the office and the corridors of the IOW.

I thank **Jelena Lovric** for HIM-SIMS analysis of the *S. marisnigri* culture.

I thank the **workshop of the IOW** for providing fast and useful handmade tools for experimental setups.

I thank the **EDV of the IOW** for immediate help with technical problems of the PC.

I thank the **R** and **Stack Overflow community** for offering an inexhaustible amount of information free of charge.

I thank **Tobias Apelt** for the permission to include some results of his Bachelor Thesis.

I thank **Solveig Kühl** for an always open door and help with every part of bureaucracy I had to struggle with.

I thank **Philipp Braun**, **René Janßen**, **Katharina Kesy**, **Simon Langer**, **Lars Möller** and **Mirco Haseler** as fellow sufferers to the aim of receiving a doctor's degree.

I thank **Franziska**, **Lina**, **Falk**, **Hendrik**, **NV**, and **Franziska** for the daily conversations about work and private life.

I thank **Jakob**, **Vivi**, **Dajana**, **Stege**, **Matze**, **Moritz**, **Katrin**, **Ron**, **Wolfer**, **Anne**, **Basti**, **Frank**, **Björni**, **Schelly**, **Lukas** und **Flo**.

I thank **Patrick**, **Bat**, **Felix**, **Manuel** and **Oizo**.

I thank **Christian Stolle**, **Judith Piontek**, **Dandan Shen** and **Jenny Fabian** for a great working atmosphere and an open ear for complaints concerning technical issues in the office.

I thank my **family** for support in every imaginable situation.

I thank **Laura Fuchs** for the last years and especially the patience throughout the last months writing this thesis.

Erklärung

Hiermit versichere ich, dass ich die vorliegende Arbeit selbstständig angefertigt und ohne fremde Hilfe verfasst habe, keine außer den von mir angegebenen Hilfsmitteln und Quellen dazu verwendet habe und die den benutzten Werken inhaltlich und wörtlich entnommenen Stellen als solche kenntlich gemacht habe.
