## PAPERS ARE PREPARING

**I still have two papers under preparations**

Paper (1): Spectral characteristics of Photocatalytic constant for Titania.

Paper (2): Photocatalytic decomposition of different dyes by photoelectrochemical.

# DEDICATION

This work is dedicated to all my family.

Especially:

My parents, who supported me along the years of my studies.

My lover, who encouraged me and supported me along all the way.

My beloved sister Salwa.

PEC	Photoelectrochemical cell
K	kinetic constant
MB	Methanol Blue
GV	Gentian Violet
BG	Brilliant Green
MO	Methyl orange
EO	Eosin
XRD	X-Ray Diffraction
Goff	Refinement parameter

SA	Surface area( $\text{m}^2\text{g}^{-1}$ )
BET	Brunauer-Emmett-Teller
$N_a$	Avogadro number ( $\text{mol}^{-1}$ )
HPLC	High-performance liquid chromatography
$0^\circ\text{C}$	degree celcius
C	Current integrated peak at different time
$C_0$	Initial integrated peak
K	Photocatalytic constant ( $\text{h}^{-1}$ )
h	Hour
$I_0$	Initial absorbance
I	Current absorbance after t time.
E	Electric field
$K_{\text{UV}}$	The photocatalytic constant under UV illumination
$K_{\text{Darkness}}$	The photocatalytic constant in darkness
$K_{\text{UV+E}}$	The photocatalytic constant by using UV illumination with electric field together

# Acknowledgments

First and foremost I am grateful the Almighty Allah, the most generous for enabling me to complete my Ph.D. thesis.

I am heartily thankful to my supervisor Prof. Dr. Eberhard Burkel for giving me this opportunity to do my PhD in his group.

I'm gratefully appreciated all the time he gave motivation, patience, guidance, enthusiasm and also helping me getting scholarship which enabled me finishing this work .

I am heartily thankful to my co-supervisor Prof. Dr. Valentin Bessergenev from the Department of Physics and Center for Marine Sciences (CCMar), Faculty of Science and Technology (FCT) and Center for Marine Sciences (CCMAR) in Algarve university.

I would like to express my deep gratitude to him for continuous support, encouragement, help, patience, enthusiasm and giving immense knowledge in my work.

I am thankful to Prof. Conceicao Mateus from the department of Chemistry, FCT and Research Center in Algarve university.

I would like to express my deep gratitude and great respect to her for giving me a lot of her time and do everything in her power to overcome the obstacles and her good remarks and advice during the preparation of this research.

I would like to express my deep gratitude to her for support and permission me to work in her laboratory.

I owe big thanks to the technical staff in the department of physics in Rostock university and departments of physics and chemical in Algarve University for their continuous help.

I am grateful to Dr. Hanan Atia from Leibniz Institute for Catalysis at the University of Rostock.

I would like to express my deep gratitude to her for support and helping me.

Special thanks to all my friends and colleagues for reading this thesis.

I am grateful to all my family for encouraging and supporting me during my study. So, my gratitude and thanks to the Yemeni Embassy represented by the cultural attached and all embassy staff and Special thanks to Taiz University which supported me.

Many thanks to Mr. Daniel Reinecke, the responsible for the erasmus<sup>+</sup> program at Rostock University for his appreciated cooperation.

This Ph.D. project was funded by the Taiz University of Yemen and the erasmus<sup>+</sup> program at Rostock University.

## Abstract

Advanced oxidation processes (AOPs), namely photocatalytic reactions can be successfully used in the field of wastewater treatment to reduce toxicity and reach the complete mineralization of the organic pollutants. AOPs are the multistep photochemical processes that start with electron-hole excitation by absorbing light on the surface of photocatalyst. This process subsequents water splitting in  $H^+$  and  $OH^-$  active radicals. These radicals interact with organic pollutants presented in water which in turn result in mineralization of pollutants.

Titanium dioxide ( $TiO_2$ ) is considered one of the most effective photocatalysts. It is a semiconductor that has a wide energy gap and three crystalline forms. These are anatase which considered as the most active photocatalyst, rutile and brookite.

Great efforts have been done during the last decades to improve photocatalytic properties of  $TiO_2$  which was prepared by different synthetic procedures in different morphological forms, like pure nanopowders, thin films and doped powders. Many efforts were done in attempts to increase photocatalytic efficiency in the visible light region.

In this work, we perform systematic studies for the spectral dependence of photocatalytic constant of  $TiO_2$  fabricated by different methods.

P25 Degussa nanopowder was used as a reference photocatalyst. On the other hand, other samples were prepared by the sol-gel process followed by instead of with different annealing procedures.

In addition, P25 Degussa powders were doped with different concentrations of cobalt. Furthermore, the thin films were prepared by Chemical Vapor Deposition (CVD) method.

It was shown that for all wavelengths used in this study (365, 405, 436, 546, and 690 nm) the photocatalytic constant is not zero but instead it increased in the shorter wavelengths for all  $TiO_2$  nanopowders (the energy gap is about 3.2 eV that corresponds to 387 nm).

Our findings are that nanopowders have some electronic states inside the energy gap between valence and conduction bands. These states can be excited by light and the electrons and holes resulting from this excitation play a significant role in photocatalysis.

Another approach for increasing the photocatalytic efficiency is by increasing the lifetime of electron-hole pairs before recombination. This can be achieved by introducing local impurities or likewise local perturbation caused by the electric field inside the photocatalysts crystal matrix or by applying an external electrical field. Different commercial dyes were used to verify their purification efficiency from water. It was shown that two simultaneous effects occur in water.

One is the electrochemical removing of the pollutant and the other is the photocatalytic degradation of the pollutant. Furthermore, the existence of the synergetic effect is confirmed. This effect can be interpreted in the framework of e-h pairs separation in the electric field which results in lifetime increase, even when this field was relatively small.

# Chapter 1

## Introduction

## 1.1 Objectives

The worldwide growth of industry is accompanied by serious issues that affect the environment. Among the top of these issues comes the problem of the contaminated water. Hence, it is not surprising that many scientists work on producing research that may help in solving this problem. For instance, the discovery of water splitting effect by Fujishima and Honda paved the way for developing advanced oxidation processes, in particular the photo-induced processes of water purification [1].

TiO<sub>2</sub> is considered as one of the most attractive transition metal oxide material in the photocatalytic application due to its unique properties such as high photostability, strong oxidation activity, highly photoactive and transparency to visible light. The commercially available for TiO<sub>2</sub> is P25 Degussa powder. This powder consists of two phases 80% anatase and 20% rutile [2].

Despite the intensive studies dedicated to photocatalysis [3], the mechanisms of such processes are not completely understood.

Probably, it should be taken into account that a photocatalytic transformation is essentially dynamic and multi-steps process in which typical time intervals lie in the nanoscale level.

As it is supposed, initially absorbed photons result in e-h pairs formation. These pairs can be recombined or can migrate to the semiconductor surface where they interact with water molecules creating H<sup>+</sup> and OH<sup>-</sup> species. These species can in turn destroy organic contaminants adsorbed on the catalyst surface. Defects of various types can play a very important role in enhancing the photocatalytic activity by creating additional electron levels that take positions between the valence and conduction bands. Oxygen vacancies and various dopants (metallic and nonmetallic) inclusions are examples of such defects. Existence of additional electron levels can manifest itself in spectral dependencies of photocatalytic constant or in presence of the photocatalytic activity, when the wavelength of excitation light is higher than the energy gap nearly which corresponds to 387 nm for TiO<sub>2</sub>.

To the best of our knowledge, the spectral dependence of photocatalytic activity has not been studied yet.

Therefore, two main strategies are chosen to be investigated throughout this work.

The first one is used to understand the spectral dependence of photocatalytic constant for different TiO<sub>2</sub> systems. This helps to understand the influence of electronic states inside the energy gap of the electronic structure.

The second one is used to separate e-h pairs in order to increase life time before recombination. Additionally, applying electrical field simultaneously with photoexcitation also provokes photoelectrochemical processes of water splitting[4]. Several methods have been used to prepare TiO<sub>2</sub> nanoparticles.

In this thesis, our focus is mainly on sol-gel method due to its advantages such as cost efficiency, relatively low temperature synthesis, stability and production of nanoparticles which have high photocatalytic activity.

Consequently, the main overall objective of this work is to prepare pure  $\text{TiO}_2$  nanoparticles with different surface areas.

Other samples used here employed the commercially available P25 Degussa powder with different concentrations of cobalt dopant.

The thin film samples used for photoelectrochemical studies were prepared by Chemical Vapor Deposition(CVD)[5] using titanium isopropoxide on Si:B p-type wafer as a substrate.

## 1.2 Literature review

A rather simplistic description of heterogeneous photocatalysis is based on the initial absorption of light by semiconductor materials.

Sunlight is a clean and natural source of light that can be utilized in the photocatalytic processes. Its wavelengths window ranges from  $10^2$  to  $10^5$  nm.

A wide of these wavelengths arrive at earth in the form of 5% UV, 50% visible light and 45% infrared.

The UV wavelength window ranges between 280 nm to 400 nm. Its wavelengths can pass through atmospheric layers and it has the possibility for a photochemical process.

TiO<sub>2</sub> photocatalyst has an indirect energy gap equal to 3.23 eV and 3.0 eV for anatase and rutile crystal modifications, respectively[1, 6].

Depending on these energy gap structures, the absorption thresholds for anatase and rutile are 383 and 413 nm, respectively.

This means that pure TiO<sub>2</sub> is only active in the UV region which is 5% of the solar spectrum whereas the visible region consists of 40% of the spectrum as referred in figure 1.1.

Several studies have employed light waves with  $\lambda$  longer than 400 nm or solar light without filtering [7, 8, 9, 10].

However, to our knowledge, the spectral dependence of photocatalysis constant has not been investigated yet.

This part is devoted to studying the photocatalytic constant by using a high-pressure mercury lamp as UV illumination and also visible lines. Different optical filters are also used to separate the lamp spectrum into different wavelengths as displayed in figure 1.2.

**Figure 1.1:** Solar radiation spectrum of the sun at sea level at zenith.  $\text{TiO}_2$  is capable of receiving excitation in the ultraviolet region of the solar spectrum which is smaller than 5 % of the total solar intensity[11].

**Figure 1.2:** Spectral absorption of mercury lamp used as a light source. Different wave-lengths are shown here, 365, 405, 436, 546 and 690 nm obtained by UV-visible spectrometer.

### 1.2.1 Principle of photocatalysis

Photocatalysis is considered as the most effective process for water and air purification from organic pollutants. This process is known as advanced oxidation process (AOPs). This process depends on the in-situ generation of highly reactive radical species, mainly hydroxyl radicals and superoxides ions which is created by photogenerated holes ( $h^+$ ) and electrons ( $e^-$ ) and consequent chemical reaction by adsorbing on the surface of photocatalyst for organic compounds[12].

This process has the ability to oxidize the organic material and mineralize the intermediates to a non-hazardous form such as carbon dioxide, nitrates and water.

Moreover, it has several advantages compared to other processes. The most important advantages are:

1. The AOP chemical reactions can be placed at relatively mild conditions, require less chemical input and the reaction time may be smaller including the temperature and pressure at ambient conditions.
2. Low cost and formation of harmless products.
3. High potential to destroy toxic compounds in various wastewater streams.
4. Complete mineralization[13].

It should be noted that the catalysis, as well as, photocatalysis is widely referred to the process that accelerates chemical reaction without consuming the photocatalyst[14].

TiO<sub>2</sub> is the most preferred material used in photocatalysis due to its numerous advantages, such as chemical stability, low cost, easy availability and high photoactivity[14, 15].

Due to its aforementioned properties, TiO<sub>2</sub> is considered an excellent photocatalyst. As depicted in figure 1.3, the mechanism of the photocatalytic reaction goes through three steps:

1. The incident photon that has the energy greater than or equal to energy gap ( $h\nu \geq E_g$ ) of the metal oxide can excite an electron from valence to conduction bands and can form photoexcited  $e^-/h^+$  in the bulk (equation1.1).

A common chain reaction describing this process is

2. The photoexcited carriers can recombine and dissipate energy (equation1.2) or these charge carriers can be trapped by Ti<sup>3+</sup> and O<sup>-</sup> defect sites in TiO<sub>2</sub> lattice [16, 17, 18].

3. The charge carriers can migrate to the catalyst surface and initiate redox reaction with adsorbates [19, 20].

The photoexcited electron in the conduction band can interact with oxygen to form superoxide radicals (Equation1.3) and produce reactive form of oxygen may interact with hydrogen ion to form hydroxyl radicals (Equation 1.4).

These hydroxyl radicals react with electron to form hydroperoxide ions (equation 1.5)

Furthermore, these ions react with hydrogen ions to form hydrogen peroxide (equation 1.6 ).

Hydroxyl radicals and hydroxide ions are formed from the hydrogen peroxide reacting with the electron in the conduction band equation1.7

In the valence band, the adsorbed water on the surface reacts with the positively charged hole to form hydroxyl radicals and hydrogen ions equation 1.8.

Lastly, those holes are directly oxidized on the catalyst surface to form hydrogen ions and hydroxyl radicals.

These radicals play an important role to oxidize the organic compounds and decompose pollutants in equations( 1.9 and 1.10).

**Figure 1.3:** Schematic diagram illustrating the mechanism of TiO<sub>2</sub> photocatalysis. This mechanism consists of two processes. The oxidation in the valence band and a reduction in the conduction band when photons have energies greater than energy gap ( $E_g$ ).

### 1.2.2 Titanium dioxide ( $\text{TiO}_2$ ) as a photocatalyst

$\text{TiO}_2$  which also known as a Titania was used as a white pigment as it has high brightness and high refractive index[21]. It is also classified as a transition metal oxide[22].

In 1972, Fujishima and Honda discovered the water splitting in the photoelectrochemical cell using  $\text{TiO}_2$  rutile single crystal as one of the potential electrode[1].

Recently,  $\text{TiO}_2$  has attracted immense interest as an ideal photocatalyst compared to its counterpart metal oxides. It is insoluble in water, thermal stability, being cheap, inert biological and chemical nature, nontoxic and non-flammable.

Besides its photostability, it is not exposed to photoanodic corrosion,  $\text{TiO}_2$  is highly photoactive and transparent to visible light[23, 24, 25].

Furthermore,  $\text{TiO}_2$  is applicable in many fields at large industrial scale such as self cleaning, catalyst support, dye-sensitized photoelectrochemical solar cell and in consumer goods.

It is also used in the pharmaceuticals sector for example, in antibacterial agent because it has strong oxidation activity and superhydrophilicity[26].

Naturally,  $\text{TiO}_2$  exists in three crystalline forms; anatase, rutile and brookite. Figure 1.4 demonstrates the units cell of these three forms of  $\text{TiO}_2$ .

These structures consist of titanium  $\text{Ti}^{4+}$  ions surrounded by six oxygen  $\text{O}^{2-}$  ions to form  $\text{TiO}_6$  octahedral configurations. These three crystal structures are different in the arrangement of the distortion with each octahedral units and in the assembly patterns of the octahedral chains [27, 28].

Although both anatase and rutile have tetrahedral structures, there are some features that differentiate them from each other. Namely, in the anatase form the octahedra are shared with their vertices while in the rutile structure the edges are shared.

Moreover, the arrangement of  $\text{TiO}_6$  octahedron is slightly larger in the anatase phase compared to the rutile phase. In anatase the Ti-Ti distances are larger whereas the Ti-O distances are shorter than in rutile.

On the other hand, the structure of brookite is different as it is orthorhombic where the vertices and edges are shared [29].

Thermodynamically, the rutile phase is the most stable. The anatase and brookite phases are metastable and they can be transformed to rutile phase under heating to (600 – 700°C)[30, 31].

It is very important to bear in mind that  $\text{TiO}_2$  is n-type semiconductor because the valence band is composed of 2p orbitals of  $\text{O}_2$  hybridized with the 3d orbitals of titanium, whereas the 3d orbitals of titanium are responsible for the conduction band [28].

Table 1.1 shows the parameters of the crystal structure of different phases of  $\text{TiO}_2$ . The anatase phase reveals the best photocatalytic activity because it has the larger surface area and porosity which produces higher number of hydroxyl groups and the catalytic sites increase.

In addition, the optimum energy gap and recombination of the e-h pair at lower rates.

Furthermore, the electron transfer from the conduction band to  $O_2$  is easier at the surface because the conduction band in the anatase phase has higher energy than that of rutile phase[32, 33].

The brookite form is not used in the experiments because it is difficult to prepare it as a pure form. Furthermore, it is unstable and it can barely be produced[34].

The photocatalytic properties of  $TiO_2$  occur when photogenerated charge carriers (holes and electrons) formed upon the absorption of the light[35, 36, 37].

In the valence band, photogenerated holes react with the molecules of adsorbed water to form the hydroxyl radicals (equation 1.8) [36].

These holes and hydroxyl radicals oxidize the organic molecules on the  $TiO_2$  surface. Superoxide radical anions are formed when the electrons in the conduction band react with the molecules of  $O_2$  (equation 1.3).

In addition,  $TiO_2$  surface under the UV light becomes superhydrophilic[38, 39].

**Table 1.1:** The crystal structure of anatase, rutile and brookite phases. a, b and c represent the cell parameters in the x, y, and z directions, respectively. [29].

Properties	Anatase	Rutile	Brookite
Crystal structure	Tetragonal	Tetragonal	Orthorhombic
Space group	$D_{4h}^{19}-4_1/amd$	$D_{2h}^{15}-Pbca$	Pbca
Lattice constant Å	a = b = 3.784 c = 9.515	a = b = 4.593 c = 2.959	a = 9.184 , b = 5.447 c = 5.145
Energy gap (eV)	3.23	3.02	3.13
Wavelength (nm)	< 390	< 415	
Applications	Photocatalyst	White paint	Dye-sensitized solar cell

**Figure 1.4:** Crystal structures of  $\text{TiO}_2$  crystalline forms: (a) rutile, (b) anatase and (c) brookite; red spheres are shown in  $\text{Ti}^{4+}$ , blue spheres are shown in  $\text{O}^{2-}$  and the unit are shown in yellow lines[28].

### 1.2.3 Doped $\text{TiO}_2$

As mentioned above,  $\text{TiO}_2$  has energy gap of 3.23 eV and 3.0 eV for anatase and rutile, respectively.

Several methods can be used to modify the band structure such as creation of composite semiconductors and doping.

The goal of this modification is necessary to reduce the e-h recombination and increase wavelength of the absorbed light in order to allow the occurrence of photocatalytic processes utilizing the natural sunlight[40, 41].

$\text{TiO}_2$  can be doped with transition and rare earth metals such as Fe, Ni, Co, V, and Lanthanides at Ti sites and non metals (like N and F) at  $\text{O}_2$  sites.

These will create trapping sites which reduce e-h pair recombination.

This facilitate the absorption in the visible region and improves the photocatalytic performance compared to the undoped photocatalyst[42, 43, 44].

Previous studies showed that doping  $\text{TiO}_2$  with transition metals (V, Fe, and Co) improved the spectral response in the visible light.

This is due to the substitution of  $\text{Ti}^{4+}$  by metallic ions in the  $\text{TiO}_2$  lattice is allowing energy states inside the energy gap structure.

Therefore, the photoactive transition is attained due to the promotion of an electron from mid-energy gap into the conduction band or excitation of an electron from the valence band of  $\text{TiO}_2$  to the mid-level of energy gap.

The dopant ions also play role on the trapping sites creation in order to reduce the recombination rate[45, 46, 47, 48, 49].

### 1.2.4 Electrolysis

The electrolysis of water is a process that is used to decompose water ( $\text{H}_2\text{O}$ ) into oxygen ( $\text{O}_2$ ) and hydrogen ( $\text{H}_2$ ) components.

In this process, all the products are safe or non-polluting compared to the process of steam reforming which produces carbon dioxide[50].

Electrolysis occurs when a sufficient energy is applied to drive the process.

In the case of the electrolytic water splitting, this energy is provided by an electric current passing through the water between anode and cathode during the electrochemical reaction[50].

The water electrolysis was first studied by using an electrostatic generator between gold electrodes to produce an electrostatic discharge[51].

Afterwards, the electrolytes of aqueous alkaline solutions were used technology still used until now[52, 53].

Later, Fujishima and Honda for the first time demonstrated photocatalytic water splitting by a photoelectrochemical cell (PEC) using  $\text{TiO}_2$ [1].

The PEC water splitting has attracted a lot of attention mostly with the aim to improve the production of efficient  $\text{H}_2$ [54, 55].

Other studies were dedicated to investigate the photoelectrochemical reactions on the surface of electrodes[4].

The photocatalytic water splitting by PEC has unique advantages compared to the other processes. These include the low costs and reasonable solar to  $\text{H}_2$  efficiency.

One more advantage is that it requires a relatively small reactor. Additionally, PEC allows  $\text{H}_2$  and  $\text{O}_2$  to be easily separated during the reaction[56].

PEC is classified into two types depending on the type of photocatalyst used in the reaction. One type is used as a photochemical cell with the powder as suspended particles in solution. Another type is the photoelectrochemical cell in which the thin film is deposited and used as photocatalyst materials to form a photoanode for performing the water splitting reaction in the solution [56].

In figure 2.6, the anode consists of Si:B p-type semiconductor substrate with  $\text{TiO}_2$  photocatalyst thin film deposited on the surface by CVD.

This  $\text{TiO}_2$  photocatalyst is used as an anode which absorbs the light and a gold wire is used as a cathode.

As known, the mechanistic model of PEC involves four steps that are performed consequently:

- Photo energy absorption, e-h pairs are generated during the process of the excitation an electron from the valence band to conduction band.
- At the photoanode, water is splitted to generate  $\text{H}^+$  and  $\text{OH}^-$  species by interaction with the e-h pairs.
- Photogenerated species are passed through an internal circuit solution to the cathode.
- At the cathode,  $\text{H}^+$  ions are reduced to  $\text{H}_2$  on the  $\text{TiO}_2$  surface[57, 58].

Surprisingly, according to our knowledge, this process was not to be used for water purification for some industrial dyes instead of photocatalytic process or in parallel with the photocatalytic process.

In this thesis, electrolysis and photocatalysis processes were studied where both processes simultaneously occur. The electric field was applied and the photocatalytic constant ( $K$ ) was investigated in dark and under illumination with UV light for the different dyes.

## 1.3 Overview of the thesis

This thesis is organized into five chapters as follows:

Chapter 1 elaborates the objectives of this thesis. The photocatalysis phenomenon and its mechanism is illustrated. Then, the basic features of  $\text{TiO}_2$  are discussed. The importance of doping on  $\text{TiO}_2$  and its influence on the properties and  $\text{TiO}_2$  structure is also explained. Finally, a brief introduction of the photoelectrochemical is addressed.

Chapter 2 describes the techniques used to characterize the physical properties of prepared pure and doped  $\text{TiO}_2$  photocatalyst powders and  $\text{TiO}_2$  thin film. Also, this chapter focuses on the preparation of pure  $\text{TiO}_2$  powders from titanium tetraisopropoxide as a precursor (TTIP) by the sol-gel method and doped  $\text{TiO}_2$  powders using the tris(diethylditiocarbamate)Co(III) (CoDtc-  $\text{Co}[\text{C}_2\text{H}_5)_2\text{NCS}_2]_3$ ). Details regarding the preparation method of  $\text{TiO}_2$  thin film by the Chemical Vapor Deposition(CVD) process are presented. Finally, this chapter addresses the basic concepts of different dyes. These include Methanol Blue(MB), Gentian Violet(GV), Brilliant Green(BG), Methyl orange(MO) and Eosin(OS) which are used as electrolytes in the photochemical cell(PEC).

Chapter 3 presents the main results obtained for pure and doped  $\text{TiO}_2$  powder materials and  $\text{TiO}_2$  thin film.

Chapter 4 includes the discussion and the analysis of the results obtained in this work presented in the previous chapter. The influence of dopant ions on  $\text{TiO}_2$  particle size, specific surface area, phase transformation and energy gap are investigated. In addition, there are discussions on the results of photocatalytic activity of  $\text{TiO}_2$  thin films deposited on Si:B substrate (that represent p-type semiconductor) by using electrochemical cell and different types of dyes under different effects. These effects are UV illumination(UV), electric field(E) applied between  $\text{TiO}_2$  thin film and gold electrode and both UV illumination and electric field(UV+E). The influence of these effects on different dyes by  $\text{TiO}_2$  thin film was investigated.

Chapter 5 provides the general conclusions of this thesis.

## Chapter 2

### Methods and experimental setup

## 2.1 Characterization

### 2.1.1 X-Ray Diffraction

X-ray diffraction technique (XRD) was used to analyze and identify  $\text{TiO}_2$  phase formation and investigate crystallographic information of the samples.

XRD patterns of  $\text{TiO}_2$  sol- gel powder were obtained by Bruker D8 Discover model diffractometer using  $\text{Cu-K}\alpha$ -radiation ( $\lambda = 0.154 \text{ nm}$ ) at room temperature, operated at 40 kV and 40 mA from  $(17-63)^\circ\text{C}$  in the lab of Rostock university.

The crystal structures of the cobalt-doped P25 Degussa have been analyzed by XRD technique at the Faculdade de Ciencias Tecnologia of Algarve university in Faro, Portugal.

Also, the crystalline phases of the thin film investigated by a high resolution PANanalytical XRD using  $\text{Cu-K}\alpha$  radiation ( $\lambda = 0.154 \text{ nm}$ ).

The accelerating voltage and the applied current were 45 kV and 30 mA, respectively. The high resolution PANanalytical XRD setup is used in  $\Theta - 2\Theta$  configuration.

All experimental data obtained from XRD experiments were collected using MAUD program and refined by Rietveld refinement method[59, 60].

All parameters such as crystal structures, phases, lattice parameters, crystal sizes and percentage of crystallinity of all samples were refined.

It is usually difficult to obtain detailed information about the structure of a polycrystalline sample because this information is lost due to the overlap of independent diffraction peaks for powders which prevents extracting any structure information. Also, the random orientation of the crystalline makes it more difficult to get structure information[61, 62, 63].

This method has worked together with Fourier analysis for broader peaks.

Other parameters such as Caglioti Paoletti and Ricci formula are replaced by crystallite size, shape and root mean square considering them as fitting parameters[63, 64]. These parameters can be refined and minimized to the residual function by using the non-linear squares algorithm which is described in this equation 2.1 :

$$y = \sum_{i=1} w_i (I_i^{\text{exp}} - I_i^{\text{cal}})^2 \quad (2.1)$$

with  $w_i$

$$w_i = \frac{1}{I_i^{\text{exp}}} \quad (2.2)$$

Where  $I_i^{\text{cal}}$  and  $I_i^{\text{exp}}$  are measured XRD experiment and theoretical calculated diffraction intensities from the powder, respectively. The calculated diffraction intensity of the powders can be expressed as:

$$I_i^{\text{cal}} = S_F \sum_{j=1}^n \frac{f_i}{(V_j)^2} \sum_{k=1}^{nL_k} |F_{K,j}|^2 S_j (2\Theta_i - 2\Theta_{k,j}) P_{k,j} A_j + \text{bkg}(2\Theta_i) \quad (2.3)$$

Where  $S_F$  is the beam intensity,  $f_i$  is the phase volume fraction,  $V_j$  is the phase cell volume and  $S_j$  is the phase scale factor, respectively.

$L_k$  is Lorentz polarization factor which depends on experimental parameters such as detector, geometry, position and the sample angle.

$F_{K,j}$  is the structure factor and it depends on the number of atoms, atomic scattering factor and the atom coordinates.

$A_j$  is the absorption coefficient of the sample. It depends on the sample thickness. And the phase have  $k = 1$  to  $n$  and  $j$  correlates peaks for the factors.

$P_{K,j}$  is the texture which depends on the angle between the crystallographic plane  $hkl$  and the preferred orientation vector.

$bkg_{2\Theta_i}$  is the background of the polynomial function in  $2\Theta$ .

Finally, the quality of refinement can be checked by two factors:  $R_{wp}$  and  $R_{exp}$ . GofF is obtained from the best fit and is must be  $<1$ . This is described in the equation below:

$$GofF = \frac{R_{wp}}{R_{exp}} \quad (2.4)$$

The parameters  $R_{wp}$  and  $R_{exp}$  can be described by the following equations:

$$R_{exp} = \sqrt{\frac{(N - P)}{\sum_{i=1}^N [w_i I_i^{exp}]^2}} \quad (2.5)$$

$$R_{wp} = \sqrt{\frac{\sum_{i=1}^N [w_i (I_i^{exp} - I_i^{cal})]^2}{\sum_{i=1}^N [w_i I_i^{exp}]^2}} \quad (2.6)$$

Where  $N$  and  $P$  are the number of points and parameters, respectively[63].

### 2.1.2 Surface area and porosity

Surface area and porosity are two important physical properties that depend on morphology of the nanostructure powders. They play a important role in photocatalysis are studied by  $N_2$  adsorption.

The gas adsorption can be classified into physisorption and chemisorption which are depending upon the bonding type.

The physisorption is the phenomenon that is used to study the morphology because it has a characteristics which makes it the most suitable for surface area determinations.

Both adsorption and desorption processes are reversible. However, it may lead to coverage the surface by multilayer adsorbate and it occurs at low temperature.

Moreover, these processes do not require activation energy and they can achieve equilibrium rapidly. As result, it is easy to calculate the surface area since the molecules are not restricted to specific sites and they are free to cover the entire surface[65, 66].

Since the late 1940s,  $N_2$  adsorption is used to determine the surface area and characteristics of porous texture for catalyst at  $N_2$  liquid temperature 77 K at 1 atm pressure [67, 68].

The adsorbed volume of  $N_2$  gas versus the relative pressure ( $\frac{p}{p_o}$ ) is used to obtain isotherm shape.

This isotherm is classified in six types according to the IUPAC classification.

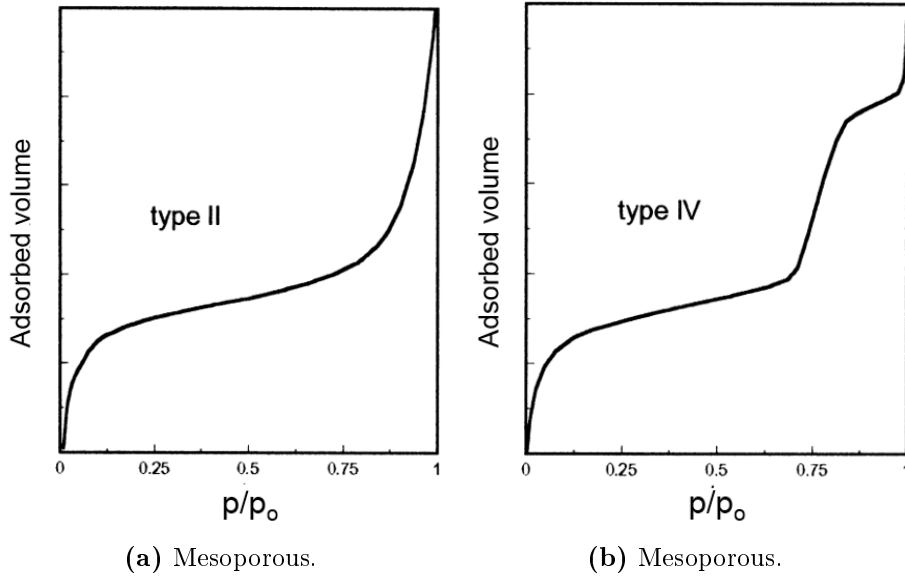

Mainly four of these types are used in the catalyst characterization [69, 70].

The main type of isotherm is II isotherm 2.1 with a  $H_3$  hysteresis characteristic as shown in 2.2.

This type belongs to the transition-metal oxide powders such as  $TiO_2$ .

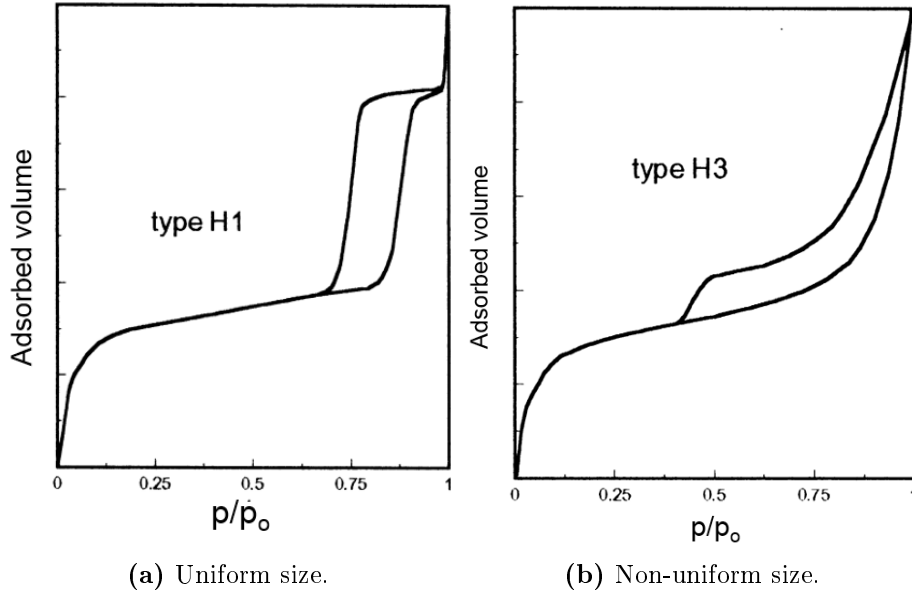

Furthermore, IUPAC has classified the pore to three types depend on their size [70, 71].

- Micropores: Size  $\leq 2$  nm.
- Ultramicropores: Size  $< 0.7$  nm.
- Mesopores:  $2 < \text{Size} \leq 50$  nm.
- Macropores: Size  $> 50$  nm.

**Figure 2.1:** The types of isotherm for a mesoporous catalysts material, adapted from reference [70].

**Figure 2.2:** The hysteresis shapes of isotherm for mesoporous catalysts material, adapted from reference[70].

Typical isotherms for mesoporous materials are shown in figures 2.1 and 2.2. They are characterized by a steady slope of adsorbed gas, especially between  $0.05 \leq \frac{p}{p_o} \leq 0.8$ . The presence of a hysteresis means the presence of open pores or different between adsorption-desorption isotherm. Inside open pores, capillary effects lead to locally higher pressure compared to the outside and capillary condensation. Therefore, the amount of gas molecules layers on the surface is not uniform and the desorption branch is not equal to the adsorption branch. The shape of the hysteresis defines the shape of the open pores, whether they are cylindrical, ink bottled or slit shaped[70].

### 2.1.2.1 Qualitative analysis

Brunauer-Emmett-Teller (BET) is the most common process used to obtain surface area and the pore size distribution. It is based on gas adsorption on the surface. The amount of gas adsorbed at a given pressure allows determining the surface area of the material[71]. This method is a cheap, fast and reliable. Also, it is very well understood and applicable in many fields. The simple form of this equation that forms the basis of the BET method for the determination of the surface area for solids can be written:

$$\frac{p}{n_a(p_o - p)} = \frac{1}{n_{\max} \cdot c} + \frac{c - 1}{n_{\max} \cdot c} \cdot \frac{p}{p_o} \quad (2.7)$$

Where  $n_{\max}$  is the amount of adsorbed at the relative pressure  $\frac{p}{p_o}$  which can be calculated by the law of ideal gas[68]. This is shown below in the equation 2.8

$$n_a = \frac{RT}{(p_{\text{inlet}} - p_{\text{equi}}) \cdot V_{\text{tube}}} \quad (2.8)$$

Where  $V_{\text{tube}}$  is the volume of the sample tube.  $p_{\text{inlet}}$  and  $p_{\text{equi}}$  are the pressure when the  $N_2$  adsorbs on the materials and the pressure inside the tube which is controlled until it reaches a constant value, respectively.

$n_{\text{max}}$  is the monolayer capacity of the adsorbate.  $p$  and  $p_o$  are the saturated vapor and the output pressure for the adsorbate, respectively, at  $N_2$  liquid temperature.

$c$  is a constant value which depends on the isotherm shape[68, 72].

According to the equation 2.7, a linear relation is obtained when  $(\frac{p}{n_a(p_o - p)})$  is plotted against  $\frac{p}{p_o}$ , from fit the line slope  $s$  and the intercept  $i$  can be determined.

The equations 2.9 and 2.10 describe  $n_{\text{max}}$  and  $c$  constant.

$$n_{\text{max}} = \frac{1}{s + i} \quad (2.9)$$

$$c = \frac{s}{i} + 1. \quad (2.10)$$

Now, it is easy to calculate the surface area (SA) of the materials by the following equation:

$$SA = (\frac{n_{\text{max}}}{22414})N_a\sigma \quad (2.11)$$

Where  $N_a$  is Avogadro number ( $6.023 \times 10^{23}$  molecules  $\text{mol}^{-1}$ ) and  $\sigma$  is the area of one molecule of  $N_2$  which is occupied on the monolayer. This value  $\sigma = 0.0162 \text{ nm}^2$  and  $22414 \text{ cm}^3 \text{gm}^{-1}$  is the volume under standard conditions of one  $N_2$  molecule which is adsorbed[73, 70].

### 2.1.2.2 Experimental details

Micromeritics ASAP-Physisorption Analyzer 2020 is used to obtain the surface area and the pore size distribution for pure P25 Degussa, doped P25 Degussa with different concentrations of cobalt. The samples were prepared by the sol-gel method. The weights of sample powders were determined before and after the measurement. Before the measurement, the samples were degassed at  $300^\circ\text{C}$  for 2 hours at 10 mmHg pressure. Then, the samples were placed at 77K temperature using  $N_2$  gas to get the isotherm shape.

Finally, the BET equation is used to calculate the specific surface area in the range of  $0.05 \leq \frac{p}{p_o} < 0.25$ .

The pore size distributions and pore areas are derived by the Barret-Joyner-Halenda (BJH) analysis with Halsey corrections in the range of  $0.42 \leq \frac{p}{p_o} < 1$  of the adsorption branches for  $N_2$  on the powders surface.

### 2.1.3 Photocatalytic activity setup

The photocatalytic process is described in section 1.2.1.

The experimental setup used to study the photocatalytic activity of the powder samples is shown in figure 2.3.

It consists of a circular reactor shown in figure 2.3 (a) which consists of magnetic stirring, Aluminum plate and three holes.

One of these holes is used to inject and collect the samples from reactor while the other holes are used to pump air inside, as shown in figure 2.3 (d).

The second part of the setup, shown in figure 2.3 (b), is the tube used to focus the radiation vertically onto the samples being studied. Also, it has a holder to fix the filters that are used in the experiments.

The third part is where the high-pressure mercury lamp (400 W, Germany) was used as a UV source shown in the figure 2.3 (c). This lamp has 5 wavelengths according to USB 4000 UV-Visible spectrometer that was used to analyze it. The wavelengths are 365 nm, 405 nm, 436 nm, 546 nm and 690 nm, respectively.

The mercury lamp was kept at approximately 14 cm away from the sample to perform the photocatalytic reaction.

Finally, syringes are used to inject the sample in the reactor and collect it for analysis. Small tubes used to collect the samples during the experiment.

This setup was built in Rostock university and all experiments were performed in chemistry department of Algarve university.

The photocatalytic degradation of Fenarimol follows the first order kinetic in equation 2.12 [74, 75, 76].

$$C = C_0 e^{-Kt}. \quad (2.12)$$

Where  $C$  is initial HPLC (High-performance liquid chromatography) chromatographic integrated peak intensities at 220 nm after adsorption-desorption equilibrium.  $C_0$  is current HPLC chromatographic integrated peak during the radiation time.  $t$  is the time in hours and  $K(\text{h}^{-1})$  is the kinetic rate constant of the degradation. The total kinetic rate constant of photocatalytic degradation can be calculated by the sum of the degradation at catalyser  $K_c$  and a photolysis under the UV light  $K_o$ .

$$K = K_c + K_o \quad (2.13)$$

The kinetic rate constant of the chemical reaction  $K_c$  is determined for the different  $\text{TiO}_2$  systems [75, 76].

#### 2.1.3.1 Experimental setup

The photocatalytic activity experiments were prepared as follows:

Firstly, Fenarimol powder ( $\text{C}_{17}\text{H}_{12}\text{Cl}_2\text{N}_2\text{O}$ ) as a reference was mixed with MilliQ  $\text{H}_2\text{O}$ .

The ratio and the amount of photocatalyst are:

Fenarimal: $\text{H}_2\text{O}$ =5 mg : 1 Litre.

Then, this solution was heated at 40°C with ultrasonic about 15 minutes for several times and kept in a dark place for one day.

After that, 20 mg of  $\text{TiO}_2$  powder was mixed with 100 ml of Fenarimal solution and kept in darkness for one day. Finally, 50 ml of the solution was injected into the reactor.

The reactor was bubbled continuously with external air under constant magnetic stirring throughout the experiment and the solution was left for 1 hour and 30 minutes in the darkness to allow saturation of the powder to establish an adsorption-desorption equilibrium.

After adsorption-desorption equilibrium, the first sample ( $T_0$ ) is taken. A light source focuses vertically at the center inside the reactor to begin the experiment. Samples treated were withdrawn from the reactor at regular interval of (10, 15 and 30) minutes.

Before analysis the sample were filtered by  $0.45\mu\text{m}$  filters to remove the photocatalyst particles. Photolytic and photocatalytic kinetics were followed using a HPLC chromatographer ( Agilent, 1220 LC System) equipped with a C18 reverse phase column (lichrocart 125-4, Lichrose Rp-18e ( $5\mu\text{m}$ )), an isocratic manual injector with the loop of  $50\mu\text{l}$  and a variable UV detector.

Mobile phase composition consists of 65% Acetonitrile and 35%  $\text{H}_2\text{O}$  and it has a flow of approximately 1 ml/min.

The wavelength at maximum absorption peak, of each indicator compound is used to monitor degradation is 220 nm.

**Figure 2.3:** The experimental setup for studying the photocatalytic activity of  $\text{TiO}_2$  powders. It consists of a circular reactor (a). A cylindrical tube to focus the radiation and hold the filters (b). The mercury lamp is used as a light source (c). Air pump is used to insert air to the reactor (d) and syringes to inject and collect sample (e). Plastic tubes are used to collect samples for analysis (f).

### 2.1.4 UV-Visible Spectroscopy

Ultraviolet-visible(UV-Vis) technique refers to absorbance and reflectance in the ultraviolet-visible spectral region.

UV-Vis absorption spectroscopy is used to measure the absorption spectra of organic dyes or powders at each wavelength.

UV-Vis technique is based on the principle of Beer-Lambert law which has the linear relationship between the absorbance and the solution concentration. It can be expressed as follows:

$$A = \varepsilon lc. \quad (2.14)$$

A is the absorption which depends on  $\log(I_0/I)$ .  $I_0$  is the incident light intensity and I is the transmitted light intensity,  $\varepsilon$  is the molar absorptivity, l is the path length through the sample and c is the sample concentration in the solution.

This technique is usually done by scanning the wavelength for 2 seconds by recording the absorbance spectra.

In this thesis, UV-Vis spectrophotometer was used to measure the absorption spectra for the  $\text{TiO}_2$  powders to study the degradation of different organic dyes by  $\text{TiO}_2$  thin film photocatalyst.

For example, the absorption at maximum  $\lambda$  of methylene blue equals to 664nm and methyl orange equals to 466nm. The photocatalytic degradation and photocatalytic constant for the different dyes are calculated by using the equation 2.15.

$$\ln \frac{I}{I_0} = -Kt \quad (2.15)$$

$I_0$  is the initial absorbance in the darkness at the beginning  $t=0$  minute and I is the absorbance after time t.

The plot  $\ln \frac{I}{I_0}$  as a function of irradiation time exhibits a straight line, whose the slope is equal to photocatalytic constant K.

Additionally, UV-Vis technique is used to calculate the optical energy gap of the samples[77].

By using the relationship between the photon energy and wavelength:

$$E = hc/\lambda \quad (2.16)$$

where h is the Planck constant ( $6.626 \times 10^{-34}$  Js), c is the speed light ( $2.998 \times 10^8$  m/s) and  $\lambda$  is the wavelength.

The optical energy gap of studied samples can be defined by equation 2.17

$$E(eV) = 1239.8/\lambda \quad (2.17)$$

## 2.2 TiO<sub>2</sub> nanoparticles synthesis

In this thesis, The focus is on TiO<sub>2</sub> nanopowders and the nanostructured thin film. Thin films were prepared by the Chemical Vapor Deposition(CVD) method. Three different powders were chosen: The first one is the commercial P25 Degussa powder which was used as a reference. The second samples are based on P25 Degussa doped with different concentrations of Co. The third samples series are these prepared by sol-gel method.

### 2.2.1 TiO<sub>2</sub> powders

#### 2.2.1.1 TiO<sub>2</sub> prepared by Sol-gel method

Several techniques such as sol-gel, hydrothermal, chemical vapor, solvothermal and microwave are used for the TiO<sub>2</sub> materials synthesis of photocatalytic applications[29]. Among all these techniques, sol-gel method has generated a large scope of interest in the preparation of inorganic ceramic and it was classified as one of the most important chemical technique for TiO<sub>2</sub> nanoparticles synthesis[78].

This method has a lot of advantages such as cost effectivity, requires relatively low temperature for synthesis, it has versatility in processing, high stability and it is used in large scale application in catalyst preparation.

Due to these advantages, it has the potential to fabricate catalysts with high purity, homogeneity, fine scale and controllable morphology[79, 80].

Furthermore, this method can be classified into two different routes that are depending on the type of titanium precursor used.

There are non-alkoxide and alkoxide route. The non-alkoxide route uses inorganic salts such as (nitrates, chlorides, sulfates, carbonates, etc.) while the alkoxide route uses metal alkoxides which is starting from materials such as (titanium isopropoxide, titanium terra isopropoxide, titanium butoxide, titanium ethoxide, etc.)[81].

The sol-gel method depends on the reactions of inorganic polymerization[82].

Generally, the sol-gel method involves these steps:

Firstly, the homogenous solution was prepared by metal alkoxide precursor dissolved in an organic solvent like alcohols.

Then, a stable sol was formed by treating the homogenous solution with a suitable reagent by adding water with the acid.

After that, the sol was converted into gel which was calcinated to get the powder[83].

A lot of parameters play a role in the sol-gel method such as the solvent type, PH of acid, the amount of water and treatment temperature.

Therefore, these parameters are very important since they have direct affect on the physical properties of the final material.

Certainly, the final material is amorphous after the drying step, but heat treatment step is very necessary to convert this material into a crystalline material[84, 85, 86, 87].

In this thesis, alkoxide route is used for  $\text{TiO}_2$  synthesis. Sol-gel process of metal alkoxide can be started with hydrolysis and condensation reactions and followed by aging and then by heat treatment to convert amorphous to crystalline nanoparticles. During hydrolysis, when water is added to  $\text{TiO}_2$ , a proton from the attacking nucleophile (water) is transferred to the alkoxide group so metal hydroxide and a small amount of alcohol are released, as illustrated in the equation 2.18

Also, a small amount of alcohol is released and acid play a role in Ti-alkoxide formation during the hydrolysis and condensation steps.

of powde And, adding the acid to the solvent enhances the reaction and splitting of Ti-OR bonds is accelerated, as shown in the equation 2.19.

In this acidic medium state, the rate of condensation reaction becomes very slow due to which this reaction occurs at the end of the chain rather than in the middle. During the condensation reaction the water and alcohol molecules are released, as shown monomers under the release of an alcohol molecule[80, 83].

where M is the titanium and R is the alkyl group -  $\text{C}_n\text{H}_{2n+1}$ .

Additionally, a mutual solvent such as an alcohol is used because water and alkoxides are immiscible[88, 89].

When the gel is formed, it contains a lot of solvents that further being removed by drying.

The period between the gel formation and its drying is known as ageing.

In this period, the gel may keep undergoing hydrolysis or condensation. The aging step is crucial to obtain strength gel without changing the pore structure and an increase of the pore size reduces the surface area through dissolution and precipitation of the particles. A scheme of the detailed synthesis is given in figure 2.4.

In this thesis, three different series of sol-gel powders were prepared by varying temperature and in dependance on the addition of  $\text{H}_2\text{O}$  and  $\text{HCl}$  during the initial preparation, this is shown in table 2.1.

**Table 2.1:** The parameters of preparation sample series for sol-gel powders. The sample of series 1 added the H<sub>2</sub>O firstly, then addition HCl. While series 2 and 4 started with acid firstly and changed temperature for series 4.

Sample	H <sub>2</sub> O	HCl	Temperature
S1	First	Second	21°C
S2	Second	First	21°C
S4	Second	First	40°C

Firstly, a precursor titanium tetra isopropoxide( TTIP )(C<sub>12</sub>H<sub>28</sub>O<sub>4</sub>Ti) was added to the solvent (Ethanol) and the solution was mixed under vigorous stirring. After that, the deionized water by burette was added to the solution and stirred for approximately half an hour.

Then, acid HCl was mixed to the previous mixture and the solution product was stirred for 5 hours at room temperature.

The reagent ratios in mole are displayed in the equation:

$$\text{TTIP} : \text{Ethanol} : \text{HCl} : \text{H}_2\text{O} = 10 : 10 : 0.3 : 10$$

Finally, drying the formed gel by spray drying process with a maximum temperature (inlet) of T<sub>max</sub>= 180°C.

These sol-gel powders are placed in ceramic crucibles and heated in vacuum furnace. The pressure of this furnace is  $2.5 \times 10^{-5}$  mbar and annealed temperature at 400°C for 3 h.

**Figure 2.4:** Scheme of sol-gel synthesis of titanium dioxide powder.

### 2.2.1.2 TiO<sub>2</sub> doped with Cobalt(Co)

TiO<sub>2</sub> doped by transition metals attracts a major interest due to its potential use in the spintronic and other electronic devices. Moreover, it is considered as one of the reducible oxides on which photocatalytic processes are based [90, 91, 92, 93].

P25 Degussa is doped with Co by using a simple approach based on the sintering of P25 Degussa nanopowder with Co. P25 Degussa powder usually contains 80% anatase and 20% rutile and it is used as a reference material.

On the other side, this powder was chosen due to its high photocatalytic performance, considered sometimes as a gold standard.

Synthesis of Co-doped TiO<sub>2</sub> nanoparticles is achieved following the preparation of the mixture of the P25 Degussa nanopowders with Co precipitate.

Four different series of P25 Degussa doped with Co were prepared which are labeled as P25:1% Co, P25:2% Co, P25:5 % Co and P25:10%Co.

These series were prepared in the following steps:

Firstly, Co precipitate was obtained by dissolving of Tris(diethylditiocarbamate)Co(III) (CoDtc- Co[C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>NCS<sub>2</sub>]<sub>3</sub>) in the chloroform (CHCl<sub>3</sub>) and consequent mixture with P25. They are drying by evaporation of chloroform under heating in air at approximately 50°C.

Then, amounts of P25 and CoDtc were chosen to prepare four different Co contents in Ti<sub>1-x</sub>Co<sub>x</sub>O<sub>2</sub> ( $x = 0.01, 0.02, 0.05$  and  $0.10$ ).

After that, powders were annealed in the furnace at 400°C for 30 min in the air in order to make decomposition of CoDtc and then they were milled after being cooled.

Finally, samples were annealed in air at 550°C for 100 hours in order to make the diffusion of the Co precipitate to the inside of TiO<sub>2</sub> particles.

## 2.3 TiO<sub>2</sub> thin film samples

TiO<sub>2</sub> has been a topic of significant interest since the beginning of the current century.

TiO<sub>2</sub> is a wide energy gap semiconductor and one of its remarkable properties is the ability for water splitting and, as consequence, the ability to be used as efficient photocatalyst for removing an organic waste from water and air.

This treatment is very important for reducing the toxic organic compounds to non-toxic compounds such as carbon dioxide, water, ammonium or nitrates and chloride ions[94].

Essentially, in an organic degradation, the use of thin films for water purification has some advantages in comparison to the use of nanopowders.

One of such advantages is that it excludes the stage of powder removal after organic compound degradation. It is also supposed that an application of external electric field can result in lowering the recombination rate between e-h pairs produced by absorbed photons and, thereby, improving the catalyst efficiency[95].

To prepare uniform thin films, CVD process is widely used. This technique is one of the most modern processes to prepare thin films.

This technique is flexible and applicable to produce multilayer thin film or doped thin film structures.

Additionally, the CVD deposition technique has advantages to produce thin films such as a good quality, high growth rates and it can control the properties[96, 97]. The CVD technique is based on chemical reactions. This technique uses liquids, different gaseous and the chemical solids as a precursor. The deposition process depends on many conditions such as vapour pressure and temperature.

The CVD deposition used to prepare a wide range variety of amorphous, single crystalline and polycrystalline thin film including semiconductors of III-V and II-VI groups.

The CVD process is considered as a chemical reaction that consists of two precursors. One of them is a metal ( precursor A) and the other is the precursor of Oxygen and Sulphur which is called precursor (B). This reaction is shown in equation 2.22.

This reaction needs more than two precursors and the interfering secondary products are presented during the reaction. This normally leads in polluting the metaloxide thin film.

This problem can be overcome by using the complex compound in chemical vapour deposition (CC-CVD). An idea is that in every molecule of complex compound precursor is present already bonded metal and oxygen (or sulphur).

In this case, the chemical reaction of precursor decomposition has different kinetics when compare to classic CVD, that leads to more perfect crystallization during thin films growing[98].

here AB is the complex compound of the precursor and OR is the possible organic. The CC-CVD method has the advantage to prepare the metal oxide inside the organic precursor. The precursor is evaporated which leads to the removal of organic rests and a pure metal oxide molecule is deposited on the substrate in Si:B. Due to this advantage, TiO<sub>2</sub> thin films are prepared by CC-CVD method[98].

### 2.3.1 TiO<sub>2</sub> thin film deposition

To prepare the TiO<sub>2</sub> thin film, titanium[isopropoxide] Ti(OPri)<sub>4</sub> (TTIP) is used as a precursor while a silicon wafer of p-type which has the resistivity of (0.002-0.005)Ωcm is used as a substrate.

The experimental setup of the CVD method, as shown in figure 2.5 consists of the following parts:

Firstly, a quartz tube with inner diameter of 35 mm, 40 mm the external diameter and the length about 300 mm is used[99].

This tube was fixed (a) inside standard vacuum apparatus with a turbo-molecular pump (ALCATEL TMP 5400 CP) creating vacuum down to  $5 \times 10^{-7}$  mbar.

Then, the tube heater was placed inside a titanium foil screen.

This heater consists of two halogen lamps (A Philips 1KW) used to heat the substrate. Also, four halogen lamps (500 W) used as a heater. Before loading, the tube was cleaned in water by detergent and rinsed in distilled water. Whereas, the substrate was immersed in sulfuric acid (95%) for about 1 hour, rinsed by distilled water and washed with acetone. Finally, it was dried by a flux of filtered air[94, 99].

TiO<sub>2</sub> thin film deposition is done by the following steps:

Firstly, the precursor is filled inside the circles of the evaporator which are at the bottom of the chamber while at the top of the chamber the substrate is fixed above the evaporator.

The cooling system was connected directly to the evaporator. The vapor source has a temperature in the range (90-210)°C.

Before the thermal treatment of the precursor, the chamber is pumped out to the pressure  $1 \times 10^{-5}$  mbar and the temperature of the substrate at 450°C to confirm the crystallization of the TiO<sub>2</sub> phase on the quartz glass substrate.

Secondly, during the deposition, when the temperature of the substrate has reached, the chamber is submerged by mixture Ar\O<sub>2</sub> gas = 100\50 fluxes rates of gas 20 ml/min. As well, the pressure of deposition was changed from  $1 \times 10^{-1}$  mbar to  $1.7 \times 10^{-1}$  mbar. The mixture of argon-oxygen atmosphere should supply enough oxygen to guarantee the formation of TiO<sub>2</sub> molecules and the burning of organic rests to avoid contamination of the thin film.

Thirdly, the evaporator is heated up to 50°C and the shutter substrate is opened to begin the chemical deposition process.

During this process the pressure inside the chamber increases until the pressure of deposition is restored and at this pressure the precursor is completely evaporated and the deposition process is finished.

**Figure 2.5:** CC-CVD setup of  $\text{TiO}_2$  thin film preparation. (a) Quartz is placed inside the chamber, (b) Evaporator and (c) Schematic diagram for preparing the  $\text{TiO}_2$  thin film by CC-CVD process[99].

### 2.3.2 Photocatalytic activity of $\text{TiO}_2$ thin film

Recently, the dyes and commercial colorants have become the focus of environmental remediation because of their natural biodegradability [100, 101].

These dyes are ineffective in the traditional wastewater treatment methods because the dyes are highly soluble in water[102].

Many researchers studied the effect of visible and UV irradiation on photocatalytic degradation of these dyes on the semiconductor nanoparticles surface.

They found that photocatalytic reaction can take place due to electron and hole transfer that occur between dyes and semiconductors directly or through intermediate water splitting.

Consequently, these dyes can degrade to a smaller material and also mineralize it to water completely or other inorganic ions. Employing these methods to degrade colored organic pollutants such as dyes has important implications because of high efficiency use of visible light or UV radiation[103, 104].

### 2.3.3 Dye materials

In this work, five dyes were used as electrolytes to study the photocatalytic activity of  $\text{TiO}_2$  thin film under UV irradiation of mercury lamp and applied electric field at potential difference of 15 Volts.

These dyes are Methanol Blue (MB), Gentian Violet (GV), Brilliant Green (BG), Methyl orange (MO ) and Eosin (EO). The chemical structures of these dyes are shown in figure2.7.

Methylene blue is a cationic dye and medication. Commonly, it is used for dyeing cotton wools and coloring paper and colorant hair. The molecular formula of MB is  $\text{C}_{16}\text{H}_{18}\text{N}_3\text{SCl}$ . It has a green dark crystalline powder and easily soluble in water at room temperature.

Moreover, it has a strong adsorption characteristics on many surfaces and good resistance to light degradation[105, 106].

Methyl Orange is an azo dye which is used in textiles, pulp and papers, and leather industry. It has the molecular formula  $\text{C}_{14}\text{H}_{14}\text{N}_3\text{NaO}_3\text{S}$ . It is vastly used as an acid-base indicator in the textiles dyeing industry and experiments[107].

Gentian Violet is a dye used to distinguish and classify bacterial species, a histological stain and also it was used as an antiseptic. The chemical formula of GV is  $\text{C}_{25}\text{H}_{30}\text{ClN}_3$ . This dye has different colors depending on the acidity degree of the solution. For example, this dye is green if the acidic solution is strong[108].

Furthermore, Brilliant Green is used as an antiseptic and it is very effective against gram-positive bacteria. The chemical formula of the dye is  $\text{C}_{27}\text{H}_{33}\text{N}_2\text{HO}_4\text{S}$  and it is not resistant to light[108, 109].

Eosin is a fluorescent dye which connects salts with eosinophilic compounds containing positive charges. It is yellow in color and  $C_{20}H_6Br_4Na_2O_5$  is the chemical formula[110].

Commercially, it has several types but the most important is Eosin Y because it is easily soluble in water and alcohol. Eosin can be used to examine under the microscope because it has the ability to distinguish between the cytoplasm of different types of cell[111].

In this thesis, the setup contains the PEC cell. This cell consists of an anode and a cathode immersed in the solution (electrolyte) and connected to an external circuit shown in figure 2.6.

The photo-electrochemical reactor (PEC) is made up from quartz glass which has 75x25 mm dimensions. The capacity of this reactor is 42 ml but the total volume of the solution is used in the experiments is about 40 ml. At the bottom side of this reactor, there are inlets for air pump.

The reactor consists of an anode and a cathode. The anode is  $TiO_2$  thin film prepared by CVD process which is connected with silver electrode glued on the top of Si:B substrate on which  $TiO_2$  thin film is deposited.

The back side of the substrate as well as other sides were isolated from electrolyte by epoxide glue in order to provide electrical connection only through  $TiO_2$  thin film. A gold metal is used as a cathode.

All these dyes were obtained through pharmacy market and are used as received. While solutions were prepared using water from a Millipore water purification unit. The concentrations of the dyes were determined in the range of validity domain of the Beer-Lambert law as mentioned in section 2.1.4 according to the sensing capability of the spectrophotometer.

**Table 2.2:** Molar concentrations of different dyes ( $\times 10^{-5}$ ) mol and  $H_2O$ . The concentration of dyes and water is different according to the sensing capability of the spectrophotometer.

Name of dye	Dyes (mol)	$H_2O$ (mol)
Methanol Blue	312	5.6
Methyl orange	1.5	28
Gentian Violet	29	28
Brilliant Green	12	28
Eosin	15	39

**Figure 2.6:** Schematic diagram of a photoelectrochemical cell(PEC) used within this work. This cell consists of an anode and a cathode. The photoanode is Si-B p-type semiconductor as a substrate with TiO<sub>2</sub> thin film photocatalyst deposited on its surface by CVD, where H<sub>2</sub>O is oxidized. The photocathode is a gold metal where H<sup>+</sup> ion is reduced to H<sub>2</sub>. Both are immersed in an electrolyte which consists of dye and connected to an external circuit.

# Chapter 3

## Results

This chapter includes the results of sample characterization and photocatalytic activity studies for nanopowders prepared by sol-gel process and TiO<sub>2</sub> thin film materials.

These studies include: XRD results obtained for pure P25 Degussa and sol-gel powders. Also, P25: $x\%$ Co ( P25 Degussa nanopowders doped with different concentrations of cobalt Co, ( $x= 1, 2, 5$ , and  $10$ )).

Furthermore, the results of surface area which based on TiO<sub>2</sub> nanopowder structure and the photocatalytic activity for TiO<sub>2</sub> different powders and different dyes by TiO<sub>2</sub> thin film is presented in details.

The samples were prepared as a powder by the sol-gel method and P25 Degussa doped with cobalt. These samples were used to study the photocatalytic activity by two methods. The first method uses a mercury lamp as a source at room temperature. The second method uses different optical filters to study spectral dependence of the photocatalytic constant for various wavelengths in the range from 365 nm to 690 nm.

On the other side, several kinds of organic pollutants were degraded by TiO<sub>2</sub> p-type thin film. The photocatalytic effect on the water includes the photocatalytic degradation of different dyes and electrochemical decomposing.

## 3.1 Powder samples

### 3.1.1 X-ray diffraction

XRD method is explained in chapter 2.1.1. The XRD patterns of pure P25 Degussa nanopowders, P25 doped with Cobalt(Co) and different samples of TiO<sub>2</sub> powders prepared by the sol-gel method. As well as, series of sol-gel powders calcined at 400°C in vacuum chamber are shown in table 3.1.

The XRD patterns for all synthesized powders via sol-gel method show broadening of peaks due to small crystallite size. This can be also be clearly seen when comparing diffraction patterns from TiO<sub>2</sub> sol-gel and P25 Degussa powders.

All the peaks shown in figure 3.1 confirm the presence of TiO<sub>2</sub> anatase and rutile phases (JCPDS: No 21 – 1272) and (JCDS No(21 – 1276)), respectively[112].

Furthermore, the crystallite size of synthesized TiO<sub>2</sub> powders were found to be 24.4 nm, 10.75 nm and 33.98 nm for  $S1$ ,  $S2$  and  $S4$ , respectively.

In comparison to P25 Degussa which was 25.6 nm, this is much smaller, except for series  $S4$ . This sample has the largest crystallite size in compared to other samples for TiO<sub>2</sub> anatase phase.

Additionally, the crystallite size of P25 has 43.3 nm for rutile which was the largest of TiO<sub>2</sub> powders. The crystallite size for  $S1$ ,  $S2$  and  $S4$  were 34.5 nm, 40.6 nm and 50.09 nm, respectively.

This significant changes in anatase and rutile phases can be taken place for the sample  $S4$ . It is higher than the other samples as shown in table 3.1.

Some peaks of diffraction patterns obtained for the samples P25: $x\%$ Co (where  $x = 0.01, 0.02, 0.05$  and  $0.10$ ) are shown in figure 3.2.

The patterns in figure 3.2 showed (101) (004) and (110) peaks.

Their peaks can be indexed as anatase and rutile phases of TiO<sub>2</sub>.

Moreover, It was shown that there are no extra peaks present or additional Co-Ti-O phases were not detected conforming that the anatase phase isn't disturbed upon doping by cobalt ions in  $\text{TiO}_2$  structure which confirms high purity of  $\text{TiO}_2$  for Co doping and phase stability of the system.

By increasing Co concentration, the peaks of XRD pattern become slightly broader indicating lattice disordering.

The results shown by [113] confirm that Co ions substitute the Ti sites and have well been incorporated in host  $\text{TiO}_2$  matrix. No signs of Co cluster phases through the whole range of Co contents were observed within the sensitivity of XRD.

The results are illustrated in table 3.1, when Co content is increased, the rutile phase is decreased.

Whereas at concentration 10% of Co the relation between anatase and rutile phases is almost the same as for P25 Degussa powder.

Therefore, it seems that Co acts as inhibitor for anatase and rutile phases transformation. This result is in contradiction with the statement presented in [114] where Co is considered as promoter for such transformation.

However, it should be noted that Co position in the diagram of elements is close to the line that divides elements as promoters and inhibitors [114].

**Table 3.1:** XRD results of pure P25, sol-gel powders and P25: $x\%$ Co nanopowders that were annealed at  $550^\circ$  for 100 h

Samples	Anatase %	Rutile %
P25 Degussa	$83.31 \pm 0.5$	$16.74 \pm 0.5$
S1	$52.98 \pm 0.3$	$47.03 \pm 0.4$
S2	$58.82 \pm 0.5$	$41.23 \pm 0.5$
S4	$74.82 \pm 0.4$	$25.23 \pm 0.5$
P25:1%Co	$75.61 \pm 0.6$	$24.40 \pm 0.5$
P25:2%Co	$78.02 \pm 0.5$	$22.02 \pm 0.5$
P25:5 % Co	$80.13 \pm 0.5$	$19.92 \pm 0.5$
P25:10 % Co	$83.02 \pm 0.4$	$17.01 \pm 0.4$

**Figure 3.1:** XRD patterns of sample powders (a) P25 Degussa as a reference and TiO<sub>2</sub> sol-gel powders (b-d).

**Figure 3.2:** XRD patterns of P25 Degussa and Degussa P25: $x\%$ Co. The peaks can be indicated as TiO<sub>2</sub> anatase phase, there are 101, 110 and 004, respectively.

### 3.1.2 Surface Area

Figure 3.3 represents the typical isotherms of  $N_2$  adsorption-desorption measured at 77 K of studied powders. There are P25 Degussa, sol- gel samples and P25: $x\%$ Co ( $x= 1, 2, 5$  and  $10$ ) with different concentrations of Co.

All powders show a type II isotherm which characterises the transition metal oxide with a H3 hysteresis.

All isotherms have a small slope from the B-point at  $\frac{P}{P_0}$  which is referring to a unique characteristic of mesoporous material family.

For the adsorption branch, the slope of the powder increases from the  $\frac{P}{P_0}$ , where a monomolecular coverage is reached until adsorbed quantity reaches to the maximum value at  $\frac{P}{P_0} = 0.98$  [70, 71].

It can be noted that the adsorbed quantity of  $N_2$  on powders directly decreases with decreasing of  $N_2$  pressure during the desorption branch which formed a narrow hysteresis that is closed at  $\frac{P}{P_0}$ . This indicates mesoporous structures inside the powder samples.

The H3 hysteresis indicates that all studied powers are involving aggregates or agglomerates of particles forming a slit-shaped pores like cubes with nonuniform sizes and shapes[71].

According to figure 3.3, all powder samples show the same isotherm II with type H3 hysteresis which is typical for P25 Degussa nanopowder[76].

The surface areas can be calculated for all samples by using equation 2.11.

In accordance with these calculations all the samples have surface area lower than that of P25 Degussa.

Furthermore, surface area increased and pore size decreased which indicates as aggregation of the particles being weaker.

According to these calculations, the sample S2 and P25:2%Co show a higher amount of  $N_2$  adsorbed compared to the others samples which displays that these samples has the largest surface area as referred in the table 3.2.

In contrary, these samples have a larger pore volume and the slimmest hysteresis compared to the other.

On the other hand, the smaller surface area and lower pore volume of the samples indicate that aggregation of the particles is stronger.

Whereas, in figure 3.4, it is shown that the pore size distribution was a broad for P25 doped similar to that of the mesoporous family and it was observed for all the powders being studied.

This organized porous structure might be significant in the photocatalytic process because they possess efficient transport pathways for reactant and product species. The surface area parameters shown in table 3.2 indicate that surface area of P25 Degussa is higher than P25 Degussa doped .

Whereas, the surface area is increased when increasing the concentration of Co at lower concentrations.

In addition, the surface area of powders P25:5%Co and P25:10%Co is decreased compared to lower concentrations of Co.

From our results, the analysis of BET for doped powders showed that a specific area is not changed drastically.

**Table 3.2:** Results calculated of specific surface area, pore size and the pore volume for P25 Degussa, sol-gel samples and P25: $x\%$ Co doped powders. The errors are numerical errors from BET and BJH calculations

Sample	SA ( $\text{m}^2\text{g}^{-1}$ )	Pore size (nm)	Pore volume( $\text{cm}^3\text{g}^{-1}$ )
P25Degussa	$57 \pm 0.34$	$2.2 \pm 0.008$	$0.179 \pm 0.008$
S1	$6.4 \pm 0.096$	$10.8 \pm 0.009$	$0.01 \pm 0.006$
S2	$73.5 \pm 1.06$	$2.37 \pm 0.001$	$0.08 \pm 0.011$
S4	$8.6 \pm 0.12$	$3.04 \pm 0.007$	$0.007 \pm 0.005$
P25:1%Co	$31.4 \pm 0.13$	$46.9 \pm 0.008$	$0.07 \pm 0.007$
P25:2%Co	$38.3 \pm 0.084$	$45.4 \pm 0.005$	$0.10 \pm 0.005$
P25:5%Co	$35.5 \pm 0.077$	$45.5 \pm 0.003$	$0.09 \pm 0.009$
P25:10%Co	$31.5 \pm 0.086$	$45.3 \pm 0.002$	$0.07 \pm 0.007$

**Figure 3.3:** Typically  $\text{N}_2$  adsorption-desorption isotherms of P25 Degussa (a).  $\text{TiO}_2$  powders prepared via sol-gel method (b) and (d). P25 doped with different concentrations of Co (d) and (f). All these isotherms belong to the mesopores materials family.

**Figure 3.4:** Pore size distribution of  $\text{TiO}_2$  studied samples. There are pure P25 Degussa Powder, sol-gel powders and P25 doped with different concentrations of Co.

### 3.1.3 UV-Visible absorption spectra

The UV-Visible absorption spectra of the studied samples were investigated.

Figure 3.5 shows UV-Vis absorption spectra of P25 Degussa as a reference material and different concentrations of Co doped P25 Degussa as well as different samples prepared by sol-gel method.

The UV-Vis spectra of studied samples are recorded in the range of 250-700 nm at room temperature as shown in figure 3.5.

This absorption spectra is shifted for doped P25 Degussa samples with increasing the concentrations of Co. However, the absorption spectra of sol-gel powders also shift dependence on crystallite size.

The energy gap and wavelengths of absorption edge are summarized in table 3.3.

The optical energy gap is calculated by extrapolation of the baseline and the absorption edge [77].

These energy gap were analyzed by using the relationship between photon energy and wavelength from equation 2.20 which are referred in figure 3.6

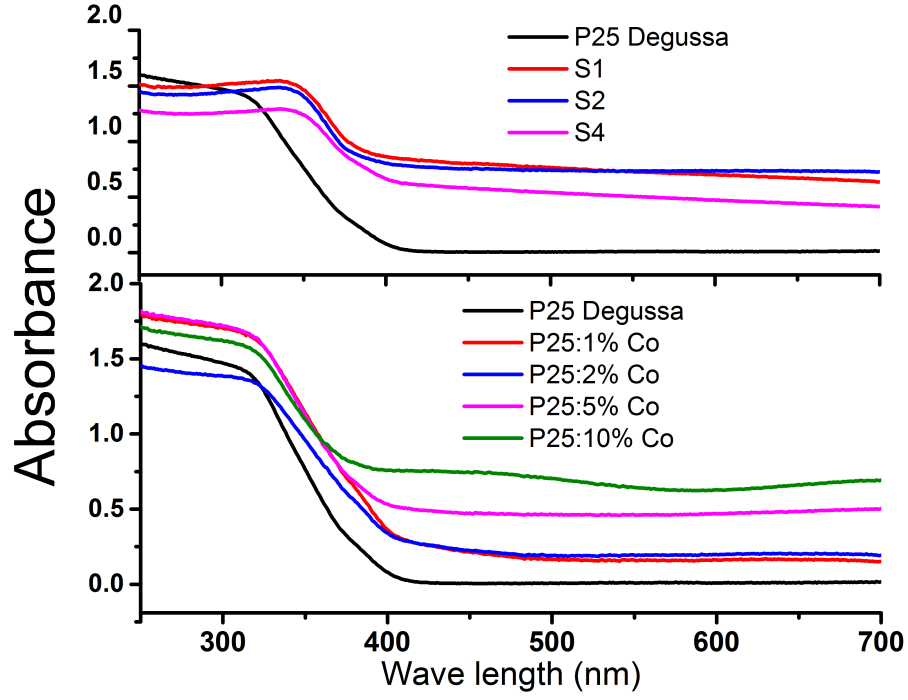

Figure 3.5 displays the spectrum absorption of P25 Degussa, P25: $x\%$ Co doped and sol-gel powder, respectively.

P25 Degussa has a sharp absorption edge at 387 nm, however, the absorption edge at (385 nm, 381 nm and 402 nm) for the series sol-gel powder were shifted towards the visible region. This shifting in absorption spectra may be enhanced the photocatalytic activity of sol-gel powder under visible light radiation.

Whilst, for the TiO<sub>2</sub> doped powders have the absorption thresholds at 399.39 nm, 401.12 nm, 397.57 nm and 380 nm for the concentrations 1%, 2%, 5% and 10% of cobalt, respectively.

The slight shift in absorption edge of doped samples at the concentration of Co increased.

Table 3.3 illustrates the decreasing in energy gap values when increasing in dopant concentrations. Whereas, the energy gap of S1 and S2 powders is slightly increased with comparing to P25 Degussa powder. While the energy gap for S4 is decreased.

**Figure 3.5:** UV-Visible absorption spectra of P25 Degussa, P25 Degussa doped with Co and pure sol-gel powders, respectively.

**Table 3.3:** Wavelengths and the optical energy gap of P25 Degussa, P25 doped with different concentrations of Co and different of sol-gel powders.

Sample	Wavelengths (nm)	$E_g$ (eV)
P25 Degussa	387.0	3.20
S1	385.2	3.22
S2	381.0	3.25
S4	402.3	3.08
P25:1%Co	399.5	3.10
P25:2%Co	401.1	3.09
P25:5%Co	397.7	3.21
P25:10%Co	380.0	3.26

**Figure 3.6:** Analysis of the optical energy gap for P25 Degussa (a), P25:5%Co and S4 is prepared by the sol-gel method in (b) and (c), respectively.

### 3.1.4 Photocatalytic activity of TiO<sub>2</sub> nanopowders

#### 3.1.4.1 Using mercury lamp

The photocatalytic activities of P25 Degussa, P25: $x\%$ Co doped and sol-gel samples were studied by observation the degradation of the Fenarimol powder (as a reference materials) dissolved in water (H<sub>2</sub>O) as mentioned in section 2.1.3.

In this work, the photocatalytic activity experiments for all samples catalysts were repeated three times.

The photocatalytic degradation is shown in figure 3.7 for P25: $x\%$ Co doped and sol-gel powders when compared to commercially P25 Degussa.

All curves of studied samples can be described as the pseudo first-order kinetic reaction which follows Langmuir Hinshelwood model[115, 74].

The good linear relationship between  $\ln \frac{C_0}{C}$  against time (t) was observed and the photocatalytic constant K extracted from the slope of the curve. That obtained the photocatalytic constant of the samples.

The results are shown in table 3.4. Under darkness, all catalyst samples have a little adsorption which can be neglected in the degradation.

However, it was shown that all catalyst samples exhibited significantly lower degradation photoactivity than P25 Degussa catalyst under the UV illumination.

Furthermore, the photocatalytic constant of P25 Degussa was found approximately 7.21 times higher than the direct photo degradation of Fenarimol powder under UV light illumination without P25 powder.

The results of the photocatalytic constant K for samples synthesized by the sol-gel method with the different surface area is given in table 3.4.

These results show that K constant decreases with decreasing the surface area of these samples.

On the other hand, the photocatalytic constant of P25 > P25:5%Co > P25:1%Co > P25:2%Co > P25:10%Co, respectively.

**Table 3.4:** Results calculated of the photocatalytic constant K(h<sup>-1</sup>) of pure P25 Degussa and sol-gel powders. Also, P25: $x\%$ Co doped at different concentrations of Co ( $x= 1, 2, 5$  and 10). All these samples are studied under mercury lamp as UV illumination and darkness in the same conditions.

Sample	K <sub>Darkness</sub>	K <sub>UV</sub>
Fenarimal	0.0412±0.001	0.212±0.02
P25Degussa	0.044±0.004	1.53±0.017
P25:1%Co	0.034±0.004	0.21±0.012
P25:2%Co	0.032±0.003	0.15 ±0.01
P25:5%Co	0.039±0.005	0.25±0.027
P25:10%Co	0.035±0.003	0.11±0.013
S1	0.039±0.01	0.39±0.03
S2	0.029±0.002	0.15±0.01

#### 3.1.4.2 Using different wavelengths

There is no study available in the literature to highlight the photocatalytic activity of different  $\text{TiO}_2$  samples by using different wavelengths in the range of 365 nm to 690 nm.

The photocatalytic activities of pure P25 Degussa,  $\text{P25}:x\%\text{Co}$  doped with different concentrations of Co and different sol-gel powders are illustrated in figure 3.8 and figure 3.9 at different wavelengths, respectively.

These results indicate the photocatalytic degradation trends of P25 Degussa.

It was faster than the other samples and it has the best photocatalytic performance at low wavelengths specially 336 nm and 405 nm, respectively.

Furthermore, the degradation of P25 is faster than the other samples under 405 nm wavelength.

It is noticed that the photocatalytic degradation is not affected by applying the high wavelength as shown in figure 3.9.

The constant K of tested samples are calculated from the slopes of curves and they are illustrated in table 4.3.

The photocatalytic constant values under short wavelength 365 nm and 405 nm of P25 Degussa attain nearly  $0.17 \text{ h}^{-1}$  and  $0.13 \text{ h}^{-1}$ , respectively.

It illustrates P25 has higher K value than doped P25 samples, as well as, 5 times, 8 times, 5 times and 2 times for  $\text{P25}:1\%\text{Co}$ ,  $\text{P25}:2\%\text{Co}$ ,  $\text{P25}:5\%\text{Co}$  and  $\text{P25}:10\%\text{Co}$ , respectively. Furthermore, P25 has higher K than the value of sol-gel powders, there are 12 times, 18 times and 5 times for S1, S2 and S4 powders, respectively.

Moreover, the photocatalytic degradation of P25 and the tested samples are very small and nearly constant. Therefore, the K constant is not equal to zero under the high wavelengths.

Moreover, figure 4.3 characterizes the relationship between the constant K and different wavelengths of pure P25, sol-gel samples powders and  $\text{P25}:x\%\text{Co}$  doped.

At shorter wavelengths, the K decreases with increasing wavelengths while it was more constant at the high wavelengths for P25 Degussa. This is the same behavior found for sample S4 powder and also similar to that of the  $\text{P25}:10\%\text{Co}$ .

In our results, the photocatalytic constant increases at short wavelengths and becomes constant at high wavelengths, as shown in figure 4.3.

**Table 3.5:** Results calculated of the photocatalytic constant  $K(h^{-1})$  for different  $TiO_2$  nanopowders. There are P25: $x\%$ Co doped with different concentrations of Co ( $x= 1, 2, 5$  and 10) and sol- gel powders under different wavelengths.

Wavelengths	365 nm	405 nm	436 nm	546 nm	690 nm

## 3.2 TiO<sub>2</sub> thin film

Many kinds of organic pollutants used to be degraded by TiO<sub>2</sub> materials.

The pure dyes are one of the important classes of pollutants for application of TiO<sub>2</sub> photocatalysts for wastewater purification.

To the best of our knowledge, there is no study in the literature dedicated to study the photocatalytic and electrochemical activity of a wide energy gap TiO<sub>2</sub> thin film in presence of applied electric field in order to remove different industrial dyes from water.

Methanol Blue(MB), Gentian violet (GV), Brilliant Green (BG), Methyl Orange(MO) and Eosin(EO) were used to verify the efficiencies of their removal from water.

There are two simultaneous effects that occur in water. One is the photocatalytic degradation of the dyes and the other is the electrochemical removing.

The photocatalytic and electrochemical performance of the synthetic TiO<sub>2</sub> thin film was studied by comparing the activities of TiO<sub>2</sub> p-type semiconductor thin films under three effects: UV illumination(UV), applied electric field(E) and UV illumination with electric field(UV+E) simultaneously under the same experimental conditions.

### 3.2.1 X-ray diffraction

Figure 3.10 shows the XRD pattern of deposited TiO<sub>2</sub> thin film on P-Si(100) as a substrate. The silicon wafer is a p-type semiconductor.

This XRD pattern displays characteristic peaks of TiO<sub>2</sub> anatase at  $2\Theta = 25.27^\circ$ ,  $54.48^\circ$ ,  $48.0^\circ$  and  $55.0^\circ$ . These are attributed to TiO<sub>2</sub> anatase diffraction in planes (101), (200), (105) and (211), respectively[116].

In addition to these peaks, some peaks of  $2\Theta = 38.5^\circ$  and  $61.68^\circ$  are also observed in this pattern which are attributed to TiO<sub>2</sub> anatase (004) and (213).

Furthermore, one peak appeared at  $2\Theta = 56.36^\circ$ . This can be indexed to plane(220) of TiO<sub>2</sub> rutile phase.

The XRD pattern is consistent with the standard XRD data for tetragonal TiO<sub>2</sub> anatase phase, (JCPDS, no 21-1272) and tetragonal TiO<sub>2</sub> rutile (JCPDS, no 21-1276)[112].

Moreover, the small peak at  $2\Theta = 32.97^\circ$  is attributed to Si (200). This peak is agreement with the results presented in reference[117].

**Figure 3.10:** XRD pattern of the  $\text{TiO}_2$  thin film deposited by the Chemical Vapor Deposited method. P-type-Si(100) was used as a substrate.

### 3.2.2 Photocatalytic activity of $\text{TiO}_2$ thin film

Figures 3.11 shows absorption spectra obtained by the UV-Vis spectroscopy in the range from 200 nm to 800 nm of different dyes without thin film in darkness.

The optical spectra of these dyes shows absorption in both UV and visible region with maximum peaks positions located at 664.5 nm, 465.07 nm, 622.04 nm, 581.51 nm and 516.68 nm for MB, MO, BG, GV and OS, respectively.

Furthermore, it is noted that there is no changes in the absorption with time of the dyes in the absence of  $\text{TiO}_2$  thin film [118].

Figure 3.12 illustrates absorption spectra of studied dyes without thin film under UV illumination (direct photolysis). As shown in figure 3.12, plots a and e, Methanol Blue and Eosin show no interaction with UV radiation.

On the other hand, the absorption spectra of the Gentian Violet, Brilliant Green and Methyl Orange slightly decreases in UV radiation as shown in figures 3.12 b, c, and d respectively.

Another set of absorption spectra experiments were performed on the same way employing a few additional conditions. Namely, mercury lamp was used as a UV source, electric field created by voltage of 15 V (Electric field applied was 15 V/0.025 m = 600 V/m) and both UV+E were applied simultaneously.

These studies are shown in figures 3.13 and 3.14. All figures, (except figure 3.13) a which belongs to the methanol blue) show a bigger reduction for the absorption in the case of E+UV than when using only E. More details can be found in the appendix A.1.1.

More clarification for the photocatalytic degradation for the different dyes can be obtained. The absorption value is attributed to the area of the main peak which is calculated by fitting the curves to a Lorentz-Gauss shape.

In our experiments, the photocatalytic degradation efficiency of the studied dyes in the case photocatalysis and electrolysis simultaneously is higher than the case when using the photocatalysis or electrolysis alone.

It can be also sublined that the simultaneous application of photocatalysis and electrolysis is more effective than the pure sum of photocatalytic and electrolytic effect. So, some kind of synergetic effect can be confirmed in our studies.

In the following, there are results of dyes degradation after irradiation for 1 hour for different conditions of experiment. The dyes absorbtion is degraded from  $I = 1$  or from 100 % at the beginning to 0.77%, 0.38%, 0.85%, 0.91% and 0.91% of MB, BG, MO, GV and EO, respectively in the case of the photocatalysis process .

In the same time, however, the degradation shows reduction in absorbtion to 0.29%, 0.38%, 0.54%, 0.83% and 0.84% in the case of the electrolysis process.

On the other hand, under two processes simultaneously, absorbtion decreases of studied dyes from 100 % to the 0.13%, 0.20%, 0.36%, 0.54% and 0.48% of MB, BG, MO, GV and EO, respectively.

Figures 3.15 a, b, c and d show the photocatalytic constants  $K$  of different dyes are obtained from equation 2.15 section 2.1.4.

As it follows from the results presented in table 3.6, the highest  $K$  constant was obtained from case of UV+E in comparison to case when only UV lamp or E field were used separately.

As shown, in the case of electrolysis and photocatalysis (UV+E), the  $K$  for MB is 4 times and 8 times higher than in the case of electrolysis (E) and photocatalysis (UV) processes used separately. However,  $K$  constant for GV is 2 times and 5 times higher than the E and UV, respectively.

Moreover,  $K$  of BG is increased to 3 times and 15 times of (UV+ E) processes in compare to processes UV and E. And for the MO, the  $K$  is 2 times and 7 times higher, respectively. Furthermore,  $K$  for OS is 6 times and 5 times higher.

Our results clearly show that the values of  $K$  constant for the UV+E case are much higher than for the E and UV cases, separately. It should be mentioned that this increase for different dyes. More details can be found in appendixA.1.2.

**Table 3.6:** Results calculated of the photocatalytic constant  $K(h^{-1})$  of different dyes. There are Methanol Blue, Gentian Violet , Brilliant Green , Methyl Orange and Eosin, respectively with  $TiO_2$  thin film under different effects.

There are:  $K_{NoTiO_2+UV}$  is photocatalytic constant of dyed without thin film,  $K_{UV}$  is photocatalytic constant under UV illumination,  $K_E$  is photocatalytic constant in the presence of electric field E and  $K_{UV+E}$  is photocatalytic constant with using UV illumination with electric field simultaneously, respectively in the same conditions.

Dyes	$K_{NoTiO_2+UV}$	$K_{UV}$	$K_E$	$K_{UV+E}$
Methanol Blue	$0.001 \pm 0.004$	$0.25 \pm 0.02$	$0.60 \pm 0.04$	$2.04 \pm 0.13$
Gentian Violet	$0.05 \pm 0.01$	$0.09 \pm 0.01$	$0.22 \pm 0.003$	$0.46 \pm 0.03$
Brilliant Green	$0.12 \pm 0.02$	$0.16 \pm 0.02$	$0.99 \pm 0.04$	$2.45 \pm 0.14$
Methyl Orange	$0.12 \pm 0.003$	$0.162 \pm 0.01$	$0.68 \pm 0.03$	$1.13 \pm 0.05$
Eosin	$0.03 \pm 0.002$	$0.079 \pm 0.01$	$0.061 \pm 0.002$	$0.38 \pm 0.02$

Plot  $\ln \frac{I}{I_0}$  as a function of radiation time to calculate K constant for different these dyes.

# Chapter 4

## Discussion

As it was already shown, the photocatalytic process is a many steps process. That includes light absorption, e-h excitation and recombination and adsorption of organic molecules on the photocatalyst surface. These molecules interact with excited electrons and holes which leads to further reactions steps of decomposition of these organic fragments.

In this part we study the influence of the surface area and porosity of nanopowders prepared using different chemical procedures on photocatalytic activity. The spectral dependence of photocatalytic constant and the influence of electrical field on photocatalytic activity of  $\text{TiO}_2$  thin films are also investigated.

The photocatalytic activity studied here for different  $\text{TiO}_2$  systems and analyzed in order to clarify the influence of different material parameters such as effective surface area, porosity, presence of dopants and external factors like electric field.

According to our knowledge, there is no study so far in literature highlighting the photocatalytic activity of  $\text{TiO}_2$  p-type with applied electric field for a decomposition of different industrial dyes. These dyes covered by this chapter include Methanol Blue (MB), Gentian violet (GV), Brilliant Green (BG), Methyl Orange (MO) and Eosin (EO).

Our discussion here will include investigating the surface area and porosity for different powders and the photocatalytic activity of different dyes with different effects.

## 4.1 Surface area and porosity

The results of surface area and pore volume of  $\text{TiO}_2$  nanopowder are listed in table 3.2. The structures studied here include the pure P25 Degussa and sol-gel nanopowders, as well as, P25 nanopowders doped with different cobalt.

The surface area of  $\text{TiO}_2$  doped increases with increasing cobalt concentrations. However, this increase experiences an excess dopant amount deposited on the  $\text{TiO}_2$  surface which in turn minimize the surface area [119].

The large surface area and wide pore size distribution may be enhanced the photocatalytic activity. The wide pores lead to ease diffusion of pollutant molecules on the catalyst powders [7].

In contrast, sol-gel powders have the smallest surface area and pores volume which results in a stronger particles aggregation.

Our analysis of the surface area of Co-doped  $\text{TiO}_2$  powders shows that, the surface area does not change significantly with the concentrations.

Moreover, the  $\text{TiO}_2$  phases show a clear independence on the Co concentrations within the temperature regimes used for the samples fabrication.

## 4.2 Analysis of energy gap

The energy gap values of different powders are investigated and listed in table 3.3. These values are plotted in figure 4.1. As shown there, the energy gap decreases with increasing the Co concentration compared to pure P25 Degussa [8, 113].

Basically, the addition of dopant creates an impurity level or most probably the formation of dopant electronic states within the  $\text{TiO}_2$  energy gap structure.

In the current situation, the intermediate electronic states are mainly originated from  $\text{Co}^{+2}$  3d states because of oxidation states in  $\text{Co}^{+2}$  contain no electrons in 3d orbitals. This means Co 3d states can overlap with the oxygen (O) 2p Ti near the valence band.

From our results, we can expect a decrease in energy gap with increasing the dopant concentration. This demonstrates that the addition of dopants introduces impurity levels which in turn changes the energy gap structure of the pure  $\text{TiO}_2$ . The optical absorption in the UV ( $\lambda = 387 \text{ nm}$ ) is attributed to the transitions from the valence band of O 2p to Ti 3d conduction band, while the impurity states of Co 3d can be overlapped with the O 2p state near the valence band.

Therefore, the low concentration of Co creates a slight variation in the energy gap [120, 8].

Our results are very well consistent with the last study presented in [113].

It proves that an observable change was introduced in  $\text{TiO}_2$  band edges upon doping with different concentrations of Co.

Therefore, we can conclude that Co doping in  $\text{TiO}_2$  may produce intermediate electron states which are originated from Co 3d and states in the energy gap.

These energy gap states result in the visible light photocatalytic activity of Co doped  $\text{TiO}_2$  powders. This is due to electronic state density in the energy gap which increases with Co concentration.

In addition, this can be attributed to the overlap of impurities energy levels with O 2p Ti levels near valence band [8].

By using UV illumination electrons can be excited from valence band of  $\text{TiO}_2$  to level states of Co near the valence band or from excited states of Co to conduction band of  $\text{TiO}_2$ .

Our results agree very well with those of reference [8], the density functional theory is used to calculate Co 3d state that is partially overlapped with O 2p states near the valence band. At lower concentrations of Co a slight variation of energy gap due to exchange interactions between s-d and p-d states causes an upward shift of valence band edge. This indicates that Co impurities have been successfully incorporated into  $\text{TiO}_2$  crystal lattice [121].

On other hand, the results of the energy gap for sol-gel samples are shown in figure 4.1 (b). As shown here, the energy gaps of S1 and S2 powders slightly increases comparing to P25 Degussa nanopowders.

On the other hand, the energy gap of S4 has an opposite behavior. This can be attributed to a higher anatase (58%) existing in S2 causing a shift of absorption spectrum towards shorter wavelengths.

On the other side, an increase in the rutile percentage will shift the absorption spectrum towards longer wavelengths [7].

The crystallite size plays a role in the energy gap variation of the powder.

Our results showed that energy gap of the S1 and S2 increases with decreasing crystallite size in these powders [122, 2, 123, 124].

However, the energy gap decreases with increasing crystallite size for S4 indicating red of the absorption spectrum [125]. This phenomenon in semiconductor nanomaterials is known as quantum size effect[10].

**Figure 4.1:** (a) The optical energy gap( $E_g$  with different Co concentrations of ( $x= 1, 2, 5$  and  $10$ )). (b)  $E_g$  of the pure P25 powder and also samples S1, S2 and S4 fabricated the sol-gel method

### 4.3 The photocatalytic activity of TiO<sub>2</sub> nanopowders with using mercury lamp

The results of the photocatalytic activity for studied samples are listed in table 3.4 and illustrated in figure 4.2. It is clear that P25 Degussa has the highest photocatalytic constant K compared to the other powder samples.

In spite of several studies of photocatalytic activities for different materials, including P25 Degussa nanopowders, it is not clear yet why this P25 powder has one of the highest photocatalytic activity constant. There are some hypotheses about this fact, for example it can be due to positive interaction between anatase and rutile particles in this powder. Another reason is the special contact between anatase and rutile phases. This maybe enough to enhance the separation of electron and holes carries and result in increasing photocatalytic efficiency of P25 Degussa[126, 127, 128].

On the other hand, the samples of P25: $x\%$ Co doped with different concentrations of Co( $x= 1, 2, 5$  and  $10$ ) exhibited significantly lower photocatalytic activity than the commercially P25 Degussa.

More specifically, the photocatalytic activity for P 25 doped catalysts decreases with increasing Co concentrations (1%, 2%, 5% and 10%).

This demonstrates that a high concentrations of Co ions act as e-h recombination centers leading to decrease in the photocatalytic efficiency[8].

This means the optimal concentration of doping ions should make the thickness of the space charger layer substantially equal to the light penetration depth is as demonstrated in reference[9].

The extremely high concentration of doping ions leads to narrowing the space charge layer and the light penetration depth exceeds the space charge layer thickness. Therefore, e-h pairs recombination become easier and hence further addition of cobalt lead to a progressive photocatalytic activity reduction.

In addition, the photocatalytic constant of P25 doped catalysts decrease with increased doping concentration because the excess doping ions occupy the grain boundaries as well as a deposit on the TiO<sub>2</sub> surface of the catalyst preventing the particles. This causes an increase in the recombination rate since the distance between the trapping sites decrease[7].

However, P25:5%Co has the highest K compared to other doped samples. That is maybe attributed to the slight improvement of the electron structure which is associated with an improvement in the visible absorption.

In addition, figure 4.2 shows the results of photocatalytic activity studies for the sol-gel powders presented in section 3.1.4.1 with different surface areas.

This results illustrate K constant decreases with increasing surface area. The large surface area is usually associated with large crystal defects which consequently favors e-h recombination and leads to reduce photocatalytic activity[27, 10].

Furthermore, the crystallite size plays a role in the photocatalytic efficiency. This K constant is lower for the powder that has the small crystallite size than the other powders. This is due to quantum size which influences the photocatalytic degradation[10].

**Figure 4.2:** The photocatalytic constants K of the studied samples under UV illumination.

#### 4.3.1 Spectral properties of the photocatalytic constant

The results of the photocatalytic degradation of studied samples are illustrated in figures 3.8 and 3.9. The photocatalytic degradation is low and nearly constant for all samples.

Furthermore, the photocatalytic degradation of P25 Degussa is faster than the other samples under the low wavelengths. This indicated that P25 powder has the best photocatalytic performance. However, the photocatalytic degradation is low and nearly constant at high wavelengths. Moreover, the K constant as a function of different wavelengths is shown in figure 4.3.

At different wavelengths, K constant of sol-gel samples especially S1 and S2 increases with 365 nm and 405 nm, while K is constant at higher wavelengths. However, S4 possesses the same behavior of P25 Degussa.

This can be attributed to the short wavelengths have enough energy to excite an electron from the valence band to the conduction band of TiO<sub>2</sub>.

So, the K constant is very strong in TiO<sub>2</sub> powders at short wavelengths 365 nm and 405 nm. However, this K constant is steady at high wavelength due to the fact the energy is not sufficient in this case.

In contrast, the photocatalytic constant increases at low wavelengths and it becomes more steady in P25:*x*%Co doped with different concentrations of Co (*x* = 1, 2, 5 and 10) at higher wavelengths. An exception, P25:10% Co shows the same behavior as pure P25. This can be explained by the electron has a sufficient energy to transport from the TiO<sub>2</sub> valence band to the mid-level near the valence band at low wavelength.

All wavelengths have the energy in the range of the TiO<sub>2</sub> energy gap. For all calculations and analysis, the K constant is normalized by the real incident light intensity.

The normalization is done by using the equations 4.1 and 4.2, respectively.

$$K_{\text{Normalized}} = \frac{K}{I_{\text{Real}}} \quad (4.1)$$

where K is photocatalytic constant for studied samples under different wavelengths and  $I_{\text{Real}}$  is the absorption of the wavelength. It is calculated from the following equation:

$$I_{\text{Real}} = I \times T_{\text{Filter}} \quad (4.2)$$

where I is the integrated area of the wavelength peak and  $T_{\text{Filter}}$  transition percentage of the filters.

The normalized values are listed in table 4.1. This table shows the photocatalytic for the studied samples.

P25 Degussa has a higher K constant at low wavelengths near the valence band, however, the K is decreased at higher wavelengths. This is due to the excited electron can easily move from the valence band to mid-level near the valence band.

The normalized values of K constant listed in table 4.1 correspond to the energy levels inside the energy gap. It should be noted that, these levels are not native energy levels created by defects of crystal structure because of impurities or crystal distortions on TiO<sub>2</sub> surface nanopowders. These levels are only corresponding to spectral energies emitted by high-pressure mercury lamp. These visible lines are cut out by the optical filter.

Photocatalytic constants K may not be in exact correspondence to resonance constant, when photons energy exactly equal to the difference between impurity energy level and energy of the conduction band.

However, this experiment clearly shows the presence of electronic levels inside the energy gap and the possibility to use visible part of the light spectrum for photocatalytic decomposition of pollutants by TiO<sub>2</sub> nanopowders in water.

More detailed analysis of the data in table 4.1 shows that similar behavior is observed for all pure powders. There are P25 Degussa, S1, S2 and S3, respectively.

For P25: $x\%$ Co with concentrations 2 and 5, a higher value of  $K_{\text{Normalized}}$  is at 405 nm in compare to 365 nm. It can be concluded also that P25:5% Co is very similar to P25 Degussa.

Moreover, the  $K_{\text{Normalized}}$  values decrease at 436 nm and 546 nm for all samples. However, all samples have a higher  $K_{\text{Normalized}}$  at 690 nm than the others 436 nm and 546 nm.

For all samples the lowest  $K_{\text{Normalized}}$  was observed at 546 nm. It should be also emphasized that for the  $\text{TiO}_2$  thin films the experiment with incident light (created by laser with adjustable wavelength) of energy a little bit lower than energy gap shows  $k = 0$ . This fact can be attributed to absence the additional energy levels inside the energy gap due to more perfect crystal structure of thin films.

**Figure 4.3:** Photocatalytic constant  $K$  as a function of different wavelengths of (a) P25 Degussa, (b) sol-gel powders and P25: $x\%$ Co doped with different concentrations of cobalt ( $x = 1, 2, 5$  and  $10$ ), respectively at room temperature in the same conditions.

**Table 4.1:** The results normalization of the photocatalytic constant  $K \times 10^7$  for studied samples at different wavelengths.

Wavelength	365 nm	405 nm	436 nm	546 nm	690 nm

## 4.4 Photocatalytic decomposition of different dyes

Dyestuffs represent a class of organic pollutants that absorb visible light.

Electron transfer processes take place between dyes and semiconductors, especially  $\text{TiO}_2$  have been studied[129, 130]. When incident light have energy higher than or equal to the energy gap. The electron excites from the VB to CB bands.

As it was already described, this transport occurs in three steps as follows:

First,  $\text{TiO}_2$  photocatalyst absorbs energy and generates photoexcited e-h pairs in the bulk. Then, the photoexcited carries are separated and migrate to the surface without recombination.

Finally, the adsorbed species are reduced and oxidized by photogenerated electrons and holes to produce  $\text{H}_2$  or  $\text{O}_2$ .

In the system of the photoelectrochemical cell (PEC) (section 2.3.3 and figure 2.6. The dyes are exposed to UV illumination excitation as well as the  $\text{TiO}_2$  surface thin film. The dye injects electrons to the  $\text{TiO}_2$  surface and it converts to cationic radicals dye\*.

In this case, the photoinduced electrons react with the dioxygen adsorbed on the  $\text{TiO}_2$  surface and generate a series of active species such as  $\text{O}_2^-$ ,  $\text{H}_2\text{O}_2$  and  $\text{OH}^\cdot$ , as depicted in figure 4.4 a and b.

**Figure 4.4:** Schematic diagram illustrating the photocatalytic of dyes (a) and  $TiO_2$  p-type semiconductor thin film with dyes using UV illumination (b).

The electron transfers very fast from the  $TiO_2$  surface to the oxidized dyes. This is due to the reduction in the oxidized dye by Ti [131]. The PEC cell includes  $TiO_2$  p-type thin film which is employed as a photo-anode or (photoelectrode). Gold metal wire was used as a cathode. Both the cathode and anode were connected to the external circuit to create e-h pairs in the dyes electrolyte. This configuration is illustrated in figure 2.6. This configuration of PEC cell permits different kind of experiments in order to emphasize the main processes that occur in PEC cell during dyes decomposition. Firstly, in the absence of thin film and without any electrical field the direct photolysis under UV irradiation can be studied and respective K constants of decomposition can be established. Secondly, in presence of thin film without electrical field photocatalytic, decomposition can be studied under UV irradiation. Thirdly, in absence of UV light but presence of electric field, direct electrolysis is the main process. Finally, all processes can be studied at the same time in the presence of all factors, namely, in presence of thin film, electric field and UV irradiation.

When a positive bias is applied between electrodes, it causes electrolysis in parallel with photocatalysis in water.

As it can be seen from table 3.6 in section 3.2.2 and figure 4.5, dyes degradation processes occur at significantly higher speed that reflects in higher degradation constants.

In this case, a positive bias causes migration of the electron(e) to catalysis surface while the holes( $h^+$ ) go through the bulk solution.

In this process, the dye accepts an electron from the  $TiO_2$  surface. Then, the electron excites dyes molecule and converts it into a cationic dye.

After that, the electrons are transferred from the excited dye to  $TiO_2$  conduction band.

All the results of UV-Visible absorption of studied dyes under UV illumination without thin film are shown in figure 3.12.

In the system of MB and EO no degradation was observed. However, the absorption spectra of the other dyes GV, BG and MO slightly decreased.

This indicates that, the oxygen pump into the solution causes dye excitation and enhances their photodegradation. This degradation increases in presence of the  $H^+$  and  $OH^-$  radicals.

Besides, an excited molecule dye is considered as an electron donor (for example  $O_2$ ) to form dye cations which are decomposed subsequently by a superoxide radical anion  $O_2^-$  or by dissolved ( $O_2$ )[132].

In the system of  $TiO_2$  thin film /dyes (in the presence of  $TiO_2$  thin film photocatalyst), the photo degradation is detected.

This is indicating that dyes interact with active radicals which is created on the  $TiO_2$  surface in the result of e-h interaction with  $H_2O$  and consequent interaction between these dyes and active radicals.

Upon UV illumination, the intensity of absorption spectra slightly decreases with increasing radiation time without wavelength shift of the band.

This is because photo-degradation processes take place in these experiments, as it illustrated in figures 3.13 and 3.14.

All the results of the photocatalytic K constant of studied dyes are listed in table 3.6. All the results show that  $TiO_2$  mediated dyes photodegradation process play an important role when compared to direct photolysis because the K constant in the system of  $TiO_2$  thin film/dyes is much higher than the K constant without thin film.

For example, the photocatalytic constant of the  $TiO_2/MB \gg MB$ ,  $TiO_2/GV > GV$ ,  $TiO_2/BG > BG$ ,  $TiO_2/MO > MO$  and  $TiO_2/EO > EO$ .

This is due to the e-h transfer and interaction with  $H_2O$  at the photocatalyst surface and consequent dyes interaction with these active species.

This transmission plays an important role in the dyes photo degradation.

It can be also indicated by the oxidation potentials of excited dyes varies from -0.33

V for Methanol Blue and 1.15 V for Eosin, respectively[133]. Moreover, Brilliant Green and Methyl Orange have 0.3 V and -1.16 V for excited singlet states of vs NHE and PH=7, respectively[134, 135] and that of the  $\text{TiO}_2$  conduction band is -0.52 V[136].

From our results, the electron transfer that occurs from the GB and thin film is more effective than the electron transfer from other dyes. That is consistent with the results on degradation constant of GB which is higher than the other dyes [137] except that of MB which has a higher photocatalytic constant.

Furthermore, upon the applied electric field, the degradation processes of all dyes are very effective because the concentration of the dyes decreasing rapidly. This degradation is higher than the degradation when using UV illumination alone. The photocatalytic results indicated that all dyes with catalysis thin film by applying the electric field showed higher photocatalytic constant than that with UV illumination alone. The highest photocatalytic activity is obtained when the UV illumination and electrical field are applied simultaneously. Compared to the other dyes, the BG is the highest K constant which is attributed to BG has the highest oxidation state.

All the results of the photocatalytic constants of all dyes with thin film are listed in table 3.6.

From this table, it is clearly seen that the K constant depends on the UV illumination and electric field.

As found here, K constant increases with applied UV illumination and electric field simultaneously.

This is attributed to the increase in e-h carriers which participate in the photocatalytic reaction.

**Figure 4.5:** This curve summarizes the relationship between the photocatalytic constant of  $\text{TiO}_2$  thin film using different dyes as electrolytes under darkness, UV illumination (UV), applied electric field (E) and UV illumination with electric field (UV+E) simultaneously, respectively in the same conditions.

This study illustrates the significant dependence of the photocatalytic activity and photocatalytic constant on the electric field.

The electric field separates the e-h pairs, as a consequence, the lifetime of the single carriers increases. However, the photocatalytic constant is lower when using UV illumination because of the e-h pairs recombination becomes very often.

This is shown in figure 4.5 which indicates a higher  $K_{\text{UV+E}}$  than  $K_{\text{UV}}$  and  $K_{\text{E}}$ .

As a consequence, the better performance found when the UV illumination and electric field are applied simultaneously. This can be attributed to produce e-h pairs and then separate them during applied two effects simultaneously.

Furthermore, the electric field has a stronger photo absorption than UV illumination. As a result, more photogenerated carriers will lead to higher photocatalytic activity.

The recent study shows that the photocatalytic constant dependent not only on the characteristics of dyes, but also it can be significantly influenced by the  $\text{TiO}_2$  features and also the applied electrical field.

It should be also noted that in according with our findings some kind of synergistic effect can be revealed. Namely, photocatalytic constant in presence of UV irradiation and electric field (E) simultaneously is greater than the sum of the photocatalytic constants for UV and applied electric field separately, according to this relation  $K_{\text{UV+E}} > K_{\text{UV}} + K_{\text{E}}$ .

We assume that, the electric potential across the  $\text{TiO}_2$  surface and  $\text{H}_2\text{O}$  attached to the oxide surface result in e-h pairs separation. In this case lifetime of e-h pairs can be significantly increased and recombination will be suppressed.

## Chapter 5

### Summary and Conclusion

The main aim of this work was to investigate the spectral dependence of the photocatalytic constant of several titanium dioxide systems.

Series of  $\text{TiO}_2$  powders were synthesized by sol-gel method by varying process parameters. These parameters represent changes in the process of adding of  $\text{H}_2\text{O}$  and  $\text{HCl}$  acid during the sample preparation experiments.

The process of the powder sample preparation also includes an increase in the fabrication temperature from room temperature for the samples S1 and S2 to  $40^\circ\text{C}$  for the sample S4.

This process changed particle size, surface area and polymorph structure which has been demonstrated by direct determination of these parameters affecting the photocatalytic activity of  $\text{TiO}_2$ .

On the other hand, the effects of dopants on the electronic states and the photocatalytic constant were studied by employing P25 Degussa, doped with different concentrations of Co.

The XRD patterns of  $\text{P25}:x\%\text{Co}$  revealed the formation of the anatase and rutile phases without any impurity phases of Co within the sensitivity of XRD.

The content of the anatase phase increases when the doping concentration of Co increased.

Moreover, the surface area of P25 Degussa doped with different concentrations of Co showed no specific changes.

On the other hand, the energy gap reduction for doped samples indicates that Co has been successfully incorporated into the  $\text{TiO}_2$  crystal lattice.

From the results shown above, we can conclude that Co doping in P25 Degussa causes no significant change in the band edge. However, it may introduce electronic states near the valence band edge in the electronic structure of  $\text{TiO}_2$ .

The results showed that P25 Degussa has the highest photocatalytic constant compared to 25 doped with cobalt (Co) and pure sol-gel  $\text{TiO}_2$  powders.

This is attributed to the special interaction between the anatase and rutile phases under UV illumination.

As it follows from Figure 4.2 for P25 Degussa powders, the photocatalytic constant is  $1.53 \text{ h}^{-1}$ . However, it is  $0.21 \text{ h}^{-1}$ ,  $0.15 \text{ h}^{-1}$ ,  $0.25 \text{ h}^{-1}$  and  $0.11 \text{ h}^{-1}$  for  $\text{P25}:x\%\text{Co}$  with different concentrations of Co ( $x= 1, 2, 5$  and  $10$ ), respectively.

The obtained values of the photocatalytic constant of the sol-gel powders were  $0.39 \text{ h}^{-1}$ ,  $0.15 \text{ h}^{-1}$  and  $0.19 \text{ h}^{-1}$  for the samples S1, S2 and S4, respectively.

These samples have different surface areas which are  $6.4 \text{ m}^2\text{g}^{-1}$ ,  $73.5 \text{ m}^2\text{g}^{-1}$  and  $8.6 \text{ m}^2\text{g}^{-1}$  for S1, S2 and S4 compared to the one of P25 Degussa which is  $57 \text{ m}^2\text{g}^{-1}$ . Also, these samples have different crystallite sizes which were  $24.4 \text{ nm}$ ,  $10.75 \text{ nm}$  and  $33.98 \text{ nm}$  for S1, S2 and S4 compared to the one of  $25.6 \text{ nm}$  of P25 Degussa.

The efficiency of the photocatalytic activity is mainly dependent on the crystalline quality, the surface area and crystallite size of the powdered samples prepared by the sol-gel method.

The photocatalytic constant decreases in these powders compared to P25 Degussa, probably due to minor crystalline quality (P25 Degussa powders were prepared at significantly higher temperatures) and coexisting anatase and rutile crystal modifications.

This conclusion can be made because both surface area and crystallite size of sol-gel powders and P25 Degussa are of the same order.

Furthermore, the sample S1 powder showed the highest photocatalytic constant compared to the series S2 and S4 powders, respectively.

On the other hand, the spectral dependence of the photocatalytic constant was studied for  $\text{TiO}_2$  nanopowders including P25 Degussa, sol-gel samples and P25 Degussa doped with different concentrations of Cobalt.

As it follows from Table 4.1 for all spectral lines presented in the light of mercury lamp some photocatalytic activity in nanopowders was observed.

Detailed analysis shows the presence of electronic states inside the main energy gap between valence and conduction bands of  $\text{TiO}_2$ . These states can produce electron-hole pairs under radiation with wave lengths higher than that of the corresponding energy gap.

It can be seen from Table 4.1 that for the wavelength  $\lambda=365$  nm the normalized photocatalytic constant  $K$  is higher for P25 Degussa ( $K=885$ ) powder, but with increase of Co concentration  $K$  increased from about  $K=117$  to  $K=462$  when Co concentration changed from 1% to 10%. For  $\lambda=405$  nm, for the sample P25:5%Co  $K$  is higher ( $K=683$ ) than for the P25 Degussa ( $K=250$ ). The same was observed for  $\lambda=436$  nm.

For  $\lambda=546$  nm all values of  $K$  are relatively low. Finally, for  $\lambda=690$  nm relatively high values of  $K$  for all Co doped samples, as well as, for P25 Degussa sample are observed. This behavior of  $K$  can be interpreted in terms of the existence of additional energy levels inside the main energy gap of  $\text{TiO}_2$  and these levels can be changed by changing the Co concentration.

Additionally, the decomposition of different dyes by  $\text{TiO}_2$  p-type semiconductor thin film prepared by the Chemical Vapor Deposition was investigated at different experimental conditions. Different dyes were used to study the photocatalytic constant of the degradation process that occurs on the surface of  $\text{TiO}_2$  thin films deposited on a Si p-type substrate.

These dyes are Methanol Blue(MB), Gentian Violet(GV), Brilliant Green(BG), MethylOrange (MO) and Eosin(OS).

In the absence of the  $\text{TiO}_2$  thin film, no change in the absorption spectrum of the dyes was observed. This indicates that the  $\text{TiO}_2$  thin film plays an important role in the dye decomposition process via the  $\text{H}_2\text{O}$  splitting on the  $\text{TiO}_2$  surface under UV illumination.

These dyes were successfully degraded by  $\text{TiO}_2$  thin film. The decrease of the absorption amplitude at each time can be explained by breaking down molecule bonds of the dyes.

This process is associated with an adsorption of the dye molecules on the thin film surface and, consequently, with its decomposition which causes notable changes of the solution color.

It was observed that the dye decomposition process also takes place without any UV illumination, but in the presence of an electrical field and in the presence of an electrical current provoked by this field. It means that the electrochemical process of the dye decomposition has a significant role which is comparable or even higher than photocatalysis. Respective degradation constants are listed in Table 3.6.

It should be noted that simultaneous application of UV irradiation and electrical field results in an additional increase of the degradation constant  $K$  leading to  $K_{UV+E} > K_{UV} + K_E$ .

This acceleration is attributed to the interaction between the dyes and the  $TiO_2$  surface.

This study sheds light on the role of the electric field that it plays on the photocatalytic activity and, consequently, on the photocatalytic constant.

This role results from its effect on the e-h pairs separation and by increasing their lifetimes. These lifetimes become even higher when using UV associated with E.

Throughout this study, the existence of the synergetic effect was confirmed. This effect can be interpreted in the framework of e-h pair separation in the electric field and, as a result, in an increase of their lifetime, even when this field was relatively small.

This synergetic effect of the electrical field and UV illumination may explain the high photocatalytic constant obtained for the Brilliant Green compared to the other dyes.
