1 Einleitung

1.1 Die embryonale kortikale Gehirnentwicklung der Maus

Die murine kortikale Entwicklung beginnt – wie auch beim Menschen – mit der Entstehung des Gehirns aus dem Ektoderm, welches neben Endoderm und Mesoderm eines der drei Keimblätter darstellt. Aus dem Ektoderm entwickelt sich bei Mäusen am Embryonalstadium (E) 7 die Neuralplatte, welche sich daraufhin beginnt einzustülpen und an E10,5 das Neuralrohr bildet (Stuhlmiller and García-Castro 2012, Chen et al. 2017). Am rostralen Ende des Neuralrohrs beginnt an E10,5 die Ausbildung von vesikulären Strukturen, von denen die am weitesten rostral gelegene das Telencephalon darstellt (Chen et al. 2017). Dieses besteht bereits aus zwei separaten Bereichen, welche sich später zu den beiden kortikalen Hemisphären entwickeln.

Zur Entwicklung dieser Strukturen wird eine gewaltige Anzahl an Zellen benötigt. Ein Großteil dieser Zellen wird direkt an den Rändern der Ventrikeln produziert, der sogenannten ventrikulären Zone (VZ). Die dort angesiedelten neuralen Stammzellen, auch radiale Gliazellen (rGZ) genannt, teilen sich in der Expansionsphase zwischen E10 und E12 überwiegend symmetrisch, d.h. aus jeder Zellteilung gehen zwei Stammzellen hervor (siehe Abbildung 1; Caviness, Takahashi and Nowakowski 1995, Di Bella et al. 2021). Dieses Schema ändert sich zu E12/E13 und die Stammzellen beginnen nun mit asymmetrischen Teilungen, d.h. es entstehen eine Stammzelle und eine intermediäre Vorläuferzelle (iVZ) oder direkt ein Neuron (Miyata et al. 2004, Englund et al. 2005, Arnold et al. 2008). Während die radiale Gliazelle in der VZ verbleibt, wandern die neuen iVZs und Neuronen entlang der Ausläufer der radialen Gliazellen nach außen. Die Neurone wandern dabei bis an den äußersten Rand und bilden die ersten Schichten des Kortex, welcher größtenteils aus 6 Schichten aufgebaut ist. Die iVZ hingegen verbleiben oberhalb der VZ und bilden dort die subventrikuläre Zone (SVZ) (Haubensak et al. 2004). In dieser teilen sich die meisten iVZ symmetrisch zu zwei Neuronen, ein Teil jedoch erzeugt durch symmetrische Teilung weitere iVZ (Haubensak et al. 2004, Miyata et al. 2004, Noctor et al. 2004, Wu et al. 2005). Zudem finden sich in der SVZ auch basale radiale Gliazellen (brGZ), welche im Gegensatz zu RGZs nur noch einen basalen Ausläufer besitzen. Diese verhalten sich wie iVZ, können jedoch zusätzlich noch asymmetrische Teilungen vollziehen, sodass die brGZ verbleibt und ein Neuron oder iVZ produziert wird (Fietz et

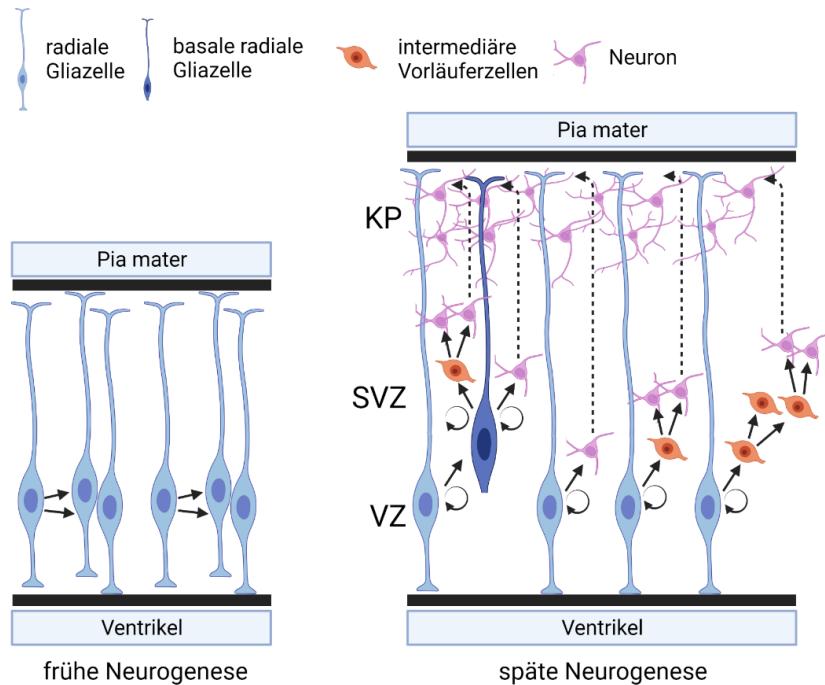

Abbildung 1: Schematische Darstellung der verschiedenen an der Neurogenese beteiligten Zellen und deren Möglichkeiten zur symmetrischen oder asymmetrischen Zellteilung während der frühen und späten Neurogenese. VZ = ventrikuläre Zone; SVZ = subventrikuläre Zone; KP = kortikale Platte. Erstellt mit BioRender.com.

al. 2010, Hansen et al. 2010). Die Art und Weise der Zellteilung innerhalb der SVZ ist dabei von entscheidender Bedeutung für die spätere Größe des jeweiligen Gehirns und stellt einen entscheidenden Unterschied in der Hirnentwicklung zwischen Mäusen und Menschen dar (Nonaka-Kinoshita et al. 2013, Pilz et al. 2013, Florio et al. 2015).

Die in der SVZ produzierten Neurone wandern wie auch die aus der VZ kommenden entlang der basalen Ausläufer der rGZ und brGZ und siedeln sich jeweils am äußersten Rand des Kortex an. Somit entsteht das für den Kortex typische *inside-out* Schema, indem die äußersten Schichten der kortikalen Platte die chronologisch jüngsten Neurone beinhalten bzw. zuletzt entstehen. So lassen sich bereits ab E11 Neurone der inneren Schichten VI und V finden, welche zwischen E11 und E16 entstehen und zwischen E15/E16 und Postnatalstadium (P) 0 ihr Maximum an Neuronen erreichen (McKenna et al. 2011, Alsiö et al. 2013, Saurat et al. 2013). Neuronen der äußeren Schichten IV bis I dagegen sind erst ab E14/E15 sichtbar und deren Anzahl steigt bis P0 kontinuierlich an (Alsiö et al. 2013, Saurat et al. 2013, Harb et al. 2016, Stepien et al. 2020). Beispielsweise entstehen nahezu alle Neuronen der Schicht II zwischen E17 und P0 (Zgraggen et al. 2012). Neben der Entstehung von Neuronen spielen Mikroglia eine entscheidende Rolle bei der kortikalen Entwicklung (Arnò et al. 2014, Tronnes et al. 2016). Mikroglia entstehen im

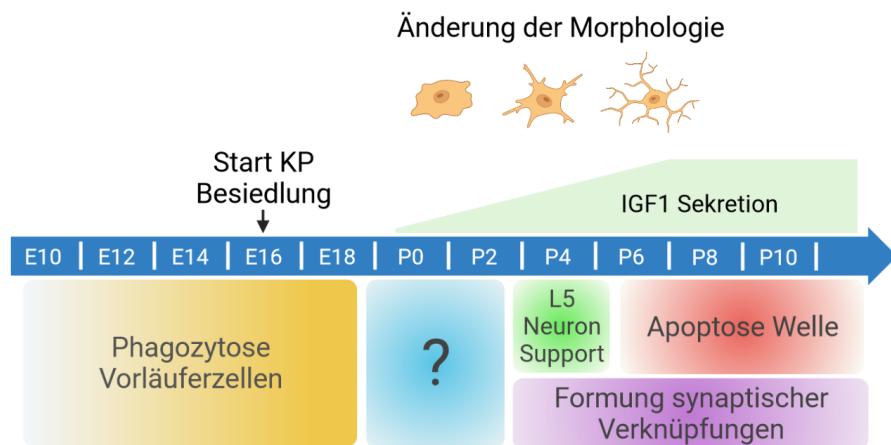

Abbildung 2: Schematische Darstellung des phänotypischen und funktionellen Umschaltens von Mikroglia im perinatalen Mauskortex. KP = kortikale Platte; IGF1 = Insulinartiger Wachstumsfaktor 1 (*Insulin like growth factor 1*). Erstellt mit BioRender.com.

Dottersack des Embryos und gelangen an ca. E11 in den sich entwickelnden Kortex, in welchem sie eine Vielzahl von Funktionen wie Phagozytose von Zellen, Förderung der Neurogenese, Erhalt spezieller Neurone und die Beeinflussung der Synapsenausbildung übernehmen (siehe Abbildung 2; (Hoshiko et al. 2012, Schafer et al. 2012, Swinnen et al. 2013, Schulz et al. 2012, Cunningham, Martínez-Cerdeño and Noctor 2013, Ueno et al. 2013, Shigemoto-Mogami et al. 2014). Chronologisch betrachtet befinden sich nahezu alle Mikroglia zunächst in den proliferierenden Zonen VZ und SVZ, in welchen sie selbst proliferieren und sowohl apoptotische als auch nicht-apoptotische Zellen phagozytieren (Alliot, Godin and Pessac 1999, Antony et al. 2011, Cunningham et al. 2013, Fricker et al. 2012). Ab P3 findet ein phänotypisches Umschalten statt, indem Mikroglia durch Sekretion von Faktoren wie Insulinartiger Wachstumsfaktor 1 (IGF1) zum Überleben von Neuronen beitragen und noch später die neuronalen Netzwerke orchestrieren (Paolicelli et al. 2011, Schafer et al. 2012, Ueno et al. 2013, Shigemoto-Mogami et al. 2014). Jedoch wird die kortikale Platte bereits ab E16 von Mikroglia besiedelt (Squarzoni et al. 2014). Deren Funktion in dieser Zeit (E16 bis P3) ist allerdings weitestgehend unbekannt und bedarf weiterer Forschung.

1.2 Sauerstoff als Einflussfaktor der Gehirnentwicklung

Eine optimale Sauerstoffversorgung stellt einen kritischen Faktor für die adäquate Entwicklung des Gehirns dar (Schneider et al. 2012, Porzionato et al. 2015). Kommt es zur

Hypoxie, etwa durch Plazentaprobleme oder Aufenthalt von Schwangeren oder Neugeborenen in großen Höhen, kann diese zu intrauteriner Wachstumsrestriktion, verringelter Neurogenese bzw. Anzahl an Neuronen sowie späteren neurologischen Einschränkungen führen (Padilla et al. 2011, Carpentier et al. 2013, Yang et al. 2013, Herrera and González-Candia 2021, Pla et al. 2020). Aber auch Hyperoxie, welche bei Frühgeburten durch iatrogene Sauerstoffbehandlung induziert wird, oder als Therapieform gegen das hypoplastische Linksherzsyndrom Anwendung findet, kann zu strukturellen Veränderungen des sich entwickelnden Gehirns führen (Felderhoff-Mueser et al. 2004, Gerstner et al. 2008, Edwards et al. 2018, Ramani et al. 2018). Problematisch daran ist, dass derartige sauerstoffbedingte Störungen im Verlauf des Lebens möglicherweise zu neurologischen Einschränkungen sowie zu Erkrankungen wie Schizophrenie oder Autismus-Spektrum-Störung führen können (Vaucher et al. 2012, Winkler-Schwartz, Garfinkle and Shevell 2014, Sola et al. 2014, Blackard et al. 2021, Wang et al. 2021). Die Ursachen dafür könnten darin begründet liegen, dass die Wirkung von Sauerstoff nicht nur auf den Energiestoffwechsel begrenzt ist, sondern dass dieser auch als wichtiger Signalfaktor fungiert (Semenza and Wang 1992). Er wirkt dabei in verschiedenen Zelltypen über Hypoxie-induzierende Faktoren (HIF), welche unter höherem Sauerstoffpartialdruck degradiert werden, unter geringen Sauerstoffpartialdruck jedoch als Transkriptionsfaktoren aktiv sind (Maxwell, Pugh and Ratcliffe 1993, Wang and Semenza 1993, Ohh et al. 2000). Dabei können HIFs maßgeblich die Eigenschaften der Stammzellen sowie Vaskularisierungsfaktoren beeinflussen (Covello et al. 2006, Tomita et al. 2003, Milosevic et al. 2009, Forristal et al. 2010). Dieser Mechanismus spielt auch in der Gehirnentwicklung eine wichtige Rolle (Tomita et al. 2003, Wagenfuhr et al. 2015, Wagenfuhr et al. 2016, Lange et al. 2016). Obwohl noch unklar ist ob Sauerstoff ausschließlich über HIFs wirkt, wurde in Wagenfuhr et al. 2015 und 2016 gezeigt, dass eine 48 h lang anhaltende maternale Hyperoxie von E14,5 bis E16,5 zu einer Vergrößerung des Kortex und auch des Mittelhirns aufgrund gesteigerter Proliferation führt (siehe Abbildung 3). Insbesondere im Kortex konnten dabei vermehrt subventrikuläre Vorläuferzellen identifiziert werden, welche in großer Anzahl normalerweise nur in höher entwickelten Gehirnen vorkommen.

Die gleiche Methode hatte dagegen zu früheren Zeitpunkten der Entwicklung kaum Auswirkungen auf den Kortex (Wagenfuhr et al. 2015). Bei Verlängerung der Hyperoxie in der frühen Entwicklung auf 72 h kommt es dagegen zu einem Umschalten der kortikalen Stammzellen hin zu vermehrter Differenzierung, sodass die Dauer der Applikation eine

wichtige Rolle zu spielen scheint (Lange et al. 2016). Jedoch zeigt eine Pilotstudie mit chronischer maternaler Sauerstofftherapie gegen das hypoplastische Linksherzsyndrom, dass, trotz verringertem Kopfumfangs bei 6 Monate alten Kindern, keine neurologischen Beeinträchtigungen nachweisbar waren (Lara et al. 2016, Edwards et al. 2018). Dies lässt darauf schließen, dass morphologische Veränderungen durch Sauerstofftherapien möglicherweise durch regulatorische Prozesse normalisiert werden. Um welche Prozesse es sich dabei handelt und warum dennoch einige Kinder nach perinatalen hyperoxischen Ereignissen neurologischen Einschränkungen unterliegen, sowie welche Rolle die Dauer einer Sauerstofftherapie spielt sind noch gänzlich unbekannt. Eine Aufklärung dieser Prozesse ist für das Verständnis der Gehirnentwicklung essentiell und wird dazu beitragen, neurologische entwicklungsbiologische Beeinträchtigungen und Erkrankungen besser zu verstehen.

1.3 Katecholamine als Einflussfaktoren der Gehirnentwicklung

Katecholamine sind wichtige Neurotransmitter in einem funktionsfähigem Gehirn. Die beiden wichtigsten Katecholamine sind Dopamin (DA), welches überwiegend in Neuronen der Substantia Nigra (SN), Ventralen Tegmentalen Areal (VTA) und dem Locus Coeruleus (LC) synthetisiert wird, und Noradrenalin (NA), welches innerhalb des Gehirns ausschließlich in Neuronen des LC synthetisiert wird. Beide Populationen entwickeln sich sehr zeitig im Gehirn: dopaminerige Neurone bilden ab E10 die SN und VTA (Bayer et al. 1995, Bye, Thompson and Parish 2012); noradrenerge Neuronen entstehen bereits an E9 und bilden den LC (Pierce 1973, Steindler and Trosko 1989). Noradrenerge Neuronen projizieren in den Kortex, den Hippocampus, den Hypothalamus, das Septum und Kleinhirn (Coyle 1977, Coyle and Kuhar 1974, Gaspar et al. 1985, Gaspar et al. 1989). Dabei werden beispielsweise alle Schichten des Kortex an P5 von noradrenergen Ausläufern durchzogen und an P14 wird das Innervationsmuster einer ausgewachsenen Maus erreicht (Verney, Molliver and Grzanna 1982, Berger et al. 1983, Berger et al. 1985, Murrin, Sanders and Bylund 2007). Dopaminerige Neuronen projizieren ebenfalls in den Kortex und Hippocampus, erreichen ihr adultes Innervationsmuster jedoch erst einige Monate nach Geburt (Kalsbeek, Matthijssen and Uylings 1989, Berger-Sweeney and Hohmann 1997). Auffällig dabei ist, dass die Entstehung der kortikalen Schichten nahezu zeitgleich mit der noradrenergen Innervation beginnt (Verney et al. 1984). Inwieweit Katecholamine die Neurogenese beeinflussen oder regulieren, ist jedoch bisher völlig unklar.

In adulten Mäusen wurde vor kurzem gezeigt, dass NA die Neurogenese im Hippocampus, der subventrikulären Zone (SVZ) und entlang des gesamten Ventrikels beeinflusst (Weselek et al. 2020). Mit Ausnahme des Hippocampus, fungiert NA dabei als Hemmstoff für die Neurogenese in der SVZ und entlang der gesamten Ventrikelachse. Dass NA je nach Bindung an verschiedene Rezeptoren fördernd oder hemmend auf die Proliferation fungiert, konnte bereits in *in vitro* Versuchen gezeigt werden (Ghiani et al. 1999, Masuda et al. 2012). Trotz dessen der Effekt von NA auf die hippocampale Neurogenese sehr gut erforscht ist gibt nur sehr wenige Studien bezüglich der periventrikulären oder embryonalen Neurogenese (Malberg et al. 2000, Kulkarni, Jha and Vaidya 2002, Jhaveri et al. 2014). Einige wenige *in vivo* Studien nutzten zudem ausschließlich toxische oder mechanische Läsionen des noradrenergen Systems, wobei nur kortikale Effekte untersucht wurden, die gegebenenfalls auf andere Einflüsse wie bestimmte Wachstumsfaktoren zurückzuführen

Einleitung

waren (Lidov and Molliver 1982, Murtha, Pappas and Raman 1990, Hassani et al. 2020). Zur Aufklärung der physiologischen Effekte von Katecholaminen, insbesondere von NA, auf die Gehirnentwicklung müssen daher systematisch Untersuchungen der Neurogenese in Abhängigkeit der jeweiligen Katecholaminlevel durchgeführt werden. In der aufgeführten Studie wird daher der DA und NA Gehalt zu verschiedenen Stadien der perinatalen Gehirnentwicklung von Mäusen untersucht und zum Ausmaß der Neurogenese korreliert.

2 Fragestellung

Die Entwicklung des Gehirns unterliegt einer Vielzahl von Einflussfaktoren und ist ein dynamischer, äußerst komplexer Prozess, welcher in weiten Teilen noch nicht verstanden ist. Komplikationen während der Entwicklung können verschiedenste neuronale entwicklungsbiologische Erkrankungen wie zum Beispiel Schizophrenie oder Autismus-Spektrum-Störung hervorrufen. Diese Erkrankungen sind weder heilbar, noch sind deren genaue Ursachen bisher bekannt. Zur möglichen Aufklärung und potenziellen Therapie solcher Erkrankungen ist es von großem Interesse, die Grundlagen der Entwicklung des Gehirns besser zu verstehen.

Die vorliegende Dissertation behandelt einen kleinen Ausschnitt dieses komplexen Prozesses. Dabei werden sowohl Sauerstoff, welcher bekanntermaßen die Neurogenese beeinflussen kann, als auch Katecholamine als Parameter der Hirnentwicklung, insbesondere des Kortex, zu bestimmten Zeitpunkten untersucht. Die konkreten Fragestellungen untergliedern sich wie folgt:

- Führt kurzzeitige maternale Hyperoxie zur dauerhaften Vergrößerung des Gehirns und Veränderung des Kortex?
- Wie werden durch maternale Hyperoxie hervorgerufene Effekte reguliert?
- Können die Effekte einer maternalen Hyperoxie durch längere Applikation noch gesteigert werden?
- Welchen Einfluss haben Katecholamine auf die Entwicklung des Gehirns?

3 Methoden

3.1 Tierhaltung, Tiermodell und Gewebepräparation

Alle Versuche mit und an Tieren erfolgten nach Genehmigung der jeweils zuständigen Landesbehörden (Landesamt für Landwirtschaft, Lebensmittelsicherheit und Fischerei Mecklenburg-Vorpommern: AZ 7221.3-1-043/16; Landesdirektion Sachsen: 24-9168.24-1/2010-5). In den Projekten wurden C57BL/6J Mäuse verwendet, welche unter 12 h/12 h Tag-Nacht-Zyklus gehalten wurden und denen Futter und Wasser *ad libitum* zur Verfügung stand. Zur Sicherstellung der entsprechenden Entwicklungsstadien wurden die Tiere zeitlich exakt verpaart, d.h. das jeweilige Männchen wurde nur eine Nacht zu den Weibchen gesetzt. Zur Gewebepräparation wurden die Tiere fachgerecht und schmerzfrei getötet, die Feten entnommen und mittels Stereomikroskop die Gehirne herauspräpariert. Diese wurde für 24 h in 4 % Paraformaldehyd fixiert, in 30 % Sukroselösung entwässert, in circa -60 °C kaltem Isopropanol schockgefroren und anschließend bis zur weiteren Verwendung bei -80 °C gelagert.

3.2 Sauerstoffbehandlung

Zur Behandlung der trächtigen Tiere wurden diese in ihren normalen Käfigen in einer auf 75% pO₂ vorgefluteten Sauerstoffkammer gehalten (siehe Abbildung 4). Die Behandlung erfolgte zur kurzzeitigen maternalen Hyperoxiebehandlung für 48 h vom Embryonalstadium (E) 14,5 bis E16,5. Zur chronischen maternalen Hyperoxiebehandlung wurden die Tiere von E5,5 bis E16,5 im 24 h Rhythmus abwechselnd in 75% Sauerstoff bzw. normaler Raumluft gehalten. Die jeweils 24 h Erholungsphase war notwendig, um das Wohl des trächtigen Tieres selbst sicher zu stellen (Wagenfuhr et al. 2015). Kurz vor der kurzzeitigen Hyperoxiebehandlung an E14,5 wurde einem Teil der Tiere das Thymidinanalogen BrdU intraperitoneal injiziert, sowie einen Tag nach der Hyperoxiebehandlung an E17,5 das Thymidinanalogen EdU.

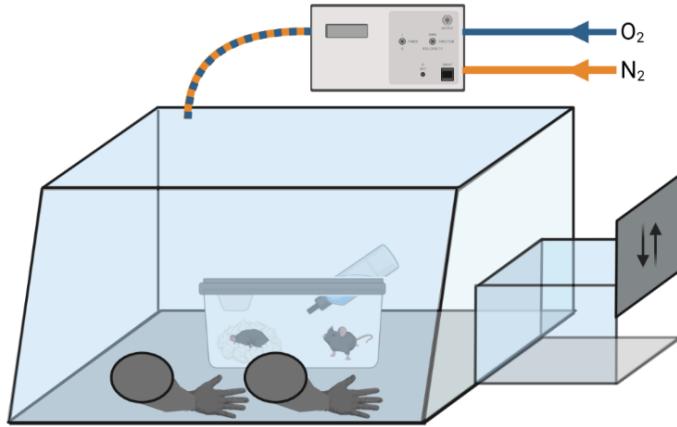

Abbildung 4: Schematische Zeichnung der verwendeten Sauerstoffkammer ITA950 (InerTec). Die aus transparentem Kunststoff bestehende Kammer verfügt über Sauerstoff- bzw. Stickstoff-Zuführungen zur exakten Einstellung des jeweilig gewünschten Sauerstoffpartialdrucks, welcher über Sensoren in der Box permanent gemessen wird. Zudem sind eine Schleuse zum Transfer der Käfig sowie Handschuhe zur Handhabung innerhalb der Kammer vorhanden. Erstellt mit BioRender.com.

3.3 Immunhistochemie

Die immunhistochemischen Analysen erfolgten mit Unterstützung von Frau Luisa Müller bezüglich NeuN Färbungen bei chronisch maternal hyperoxigenierten Tieren und maßgeblich durch Grit Weselek bezüglich der Färbungen und Analysen zur katecholaminergen Innervation des sich entwickelnden Gehirns. Zur immunhistochemischen Analyse verschiedener Marker wurden die Gehirne mittels Kryomikrotom koronar in 20 µm dünne Scheiben geschnitten und direkt auf Objektträger aufgezogen. Die Schnitte wurden mittels TBST gewaschen und zur Antigendemaskierung für 30 min in 95 °C heißem Zitratpuffer bzw. für BrdU-Färbungen bei 37 °C in 2 N HCl inkubiert. Nach erneutem Waschen erfolgte die Permeabilisierung und das Blockieren unspezifischer Bindungen mittels 0,2 % Triton-X Lösung bzw. mittels 10% Esel-Serum. Anschließend wurden die Schnitte bei 4 °C über Nacht mit verschiedenen Primärantikörpern inkubiert (Tabelle 1), gewaschen und mit Sekundärantikörper für 90 min bei Raumtemperatur inkubiert. Abschließend wurden die Schnitte 3 min mit Höchstlösung zur Kernfärbung bedeckt und mittels Fluoromount-G eingedeckelt. Die Analyse der Präparate erfolgte an verschiedenen Mikroskopen: Zeiss AxioObserver mit Apotome, Zeiss LSM900 mit AiryScan, Zeiss LSM 700 oder Leica DM IRE2.

3.4 Analyse der Katecholamine

Zur Analyse der Katecholamine wurden ca. 200 µm Gewebe rund um die Ventrikel verschiedener Gehirnareale entfernt, gewogen und in Perchlorsäure homogenisiert (durchgeführt von Grit Weselek). Die Proben wurden bei 48000 g zentrifugiert und 50 µl des jeweiligen Überstandes wurden in einem Hochleistungs-Flüssigkeitschromatographie (High-Performance Liquid Chromatography, HPLC) System auf ihren Dopamin- und Noradrenalin-Gehalt hin untersucht (durchgeführt von Manfred Gerlach). Dabei kam ein Agilent 1100 System mit Nukleosil 120-5C18 reversen Phase Säule, Elektrochemischen Detektor und Agilent Chem Station for LC9D zum Einsatz, wobei das Detektionslimit bei 0,1 ng Katecholamine pro ml Probe lag.

4 Ergebnisse

4.1 Hyperoxygenation During Mid-Neurogenesis Accelerates Cortical Development in the Fetal Mouse Brain

Franz Markert & Alexander Storch

Frontiers in Cell and Developmental Biology, 2022, Band 10, Artikel 732682

Zusammenfassung:

In dieser Studie wurde untersucht, ob die Effekte einer kurzzeitigen maternalen Hyperoxie zu dauerhaften Veränderungen im Gehirn führt. Dazu wurden trächtige C57BL/6J Mäuse von Embryonalstadium (E) 14,5 bis E16,5 in 75% Sauerstoff gehalten und die Feten bzw. Jungtiere zu E16,5, Postnatalstadium (P) 0,5 und P3,5 auf den Status ihrer kortikalen Entwicklung hin untersucht. Die immunhistochemische Analyse zeigte, dass die Sauerstoffbehandlung zu einer beschleunigten Neurogenese führt, welche sich in einem bis P0,5 anhaltenden vergrößerten Kortex und mehr kortikalen Neuronen äußert, an P3,5 jedoch wieder normalisiert ist. Im speziellen wird durch die beschleunigte Neurogenese die Anzahl an Ctip2⁺ Schicht V Neuronen an E16,5 gesteigert und adäquat zwischen P0,5 und P3,5 an das Level der Kontrolltiere angepasst. Diese Normalisierung erfolgt unter Beteiligung von CD68^{+/Iba1⁺ aktiven Mikroglia, welche Ctip2⁺ Zellen angreifen und vermehrt Ctip2⁺ Partikel phagozytieren, ohne dass diese Zeichen von Apoptose aufweisen. Insgesamt zeigt sich, dass kurzzeitige maternale Hyperoxie zu einem transienten Überschuss von Schicht V Neuronen führt, welcher jedoch kurz nach Geburt wieder normalisiert wird, sodass keine persistenten Effekte nachweisbar sind. Die Studie ermöglicht neue Einblicke in die Effekte von Sauerstoff, die Entwicklung der kortikalen Schicht V und die Beteiligung von Mikroglia während der Gehirnentwicklung.}

Hyperoxygenation During Mid-Neurogenesis Accelerates Cortical Development in the Fetal Mouse Brain

Oxygen tension is well-known to affect cortical development. Fetal brain hyperoxygenation during mid-neurogenesis in mice (embryonic stage E14.5. to E16.5) increases brain size evoked through an increase of neuroprecursor cells. Nevertheless, it is unknown whether these effects can lead to persistent morphological changes within the highly orchestrated brain development. To shed light on this, we used our model of controlled fetal brain hyperoxygenation in time-pregnant C57BL/6J mice housed in a chamber with 75% atmospheric oxygen from E14.5 to E16.5 and analyzed the brains from E14.5, E16.5, P0.5, and P3.5 mouse embryos and pups via immunofluorescence staining. Mid-neurogenesis hyperoxygenation led to an acceleration of cortical development by temporal expansion of the cortical plate with increased NeuN⁺ neuron counts in hyperoxic brains only until birth. More specifically, the number of Ctip2⁺ cortical layer 5 (L5) neurons was increased at E16.5 and at birth in hyperoxic brains but normalized in the early postnatal stage (P3.5). The absence of cleaved caspase 3 within the extended Ctip2⁺ L5 cell population largely excluded apoptosis as a major compensatory mechanism. Timed BrdU/EdU analyses likewise rule out a feedback mechanism. The normalization was, on the contrary, accompanied by an increase of active microglia within L5 targeting Ctip2⁺ neurons without any signs of apoptosis. Together, hyperoxygenation during mid-neurogenesis phase of fetal brain development provoked a specific transient overshoot of cortical L5 neurons leading to an accelerated cortical development without detectable persistent changes. These observations provide insight into cortical and L5 brain development.

Keywords: oxygen, hyperoxia, corticogenesis, neural stem cells, apoptosis, brain development, microglia, cortical layers

Abbreviations: CC3, cleaved caspase 3; CP, cortical plate; Ctip2, chicken ovalbumin upstream promoter transcription factor-interacting protein 2; E, embryonic day; L, layer; NeuN, neuronal nuclear protein; RBFOX3, RNA binding protein fox-1 homolog 3; OSVZ, outer subventricular zone; P, postnatal stage; Pax6, paired box 6; PBS, phosphate buffered saline; Satb2, special AT-rich sequence-binding protein 2; SVZ, subventricular zone; Tbr1, T-box brain protein 1; Tbr2, T-box brain protein 2; TBST, Tris buffered saline/Tween 20; vGluT2, vesicular glutamate transporter 2; VZ, ventricular zone.

INTRODUCTION

Oxygen tension during development is known to critically affect brain development (Fagel et al., 2006; Schneider et al., 2012; Porzionato et al., 2015; Wagenfuhr et al., 2015; Lange et al., 2016; Wagenfuhr et al., 2016). Thereby, the effects depend on timing and intensity of oxygen application: while short-term hyperoxygenation is able to enhance neurogenesis and brain size, chronic hyperoxygenation can lead to adverse effects (Wagenfuhr et al., 2015; Wagenfuhr et al., 2016; Markert et al., 2020). Indeed, short-term hyperoxygenation during mid-neurogenesis of fetal mouse brain development (embryonic stages E14.5 to E16.5) leads to an immediate expansion of a distinct proliferative cell population basal of the subventricular zone (SVZ) constituting a new neurogenic cell layer similar to the outer SVZ (OSVZ), which contributes to corticogenesis by heading for deeper cortical layers as a part of the cortical plate (CP) (Wagenfuhr et al., 2015). Finally, the number of *Ctip2⁺* neurons in the deeper layer 5 (L5) of the CP projecting into various brain regions is markedly increased (Hattox and Nelson 2007; Oswald et al., 2013; Wagenfuhr et al., 2015). This phenomenon is of high interest, since alterations within the cortical L5 cell population are directly linked to diseases such as schizophrenia (Kolomeets and Uranova 2019; Mi et al., 2019), which is also linked with oxidative stress and various other factors during development (Chew et al., 2013; Górný et al., 2020). Despite these known effects of maternal hyperoxygenation with subsequent changes of the oxygen tension of brain tissue *in utero*, a pilot study applying maternal oxygenation in humans, although in a more chronic treatment scheme, shows initial morphological changes of the head, but no differences in neurodevelopmental testing of the children (Edwards et al., 2018). These results raise not only concerns about the safety of maternal hyperoxygenation therapy (Rudolph 2020) but also the questions whether and how the brain is able to better compensate for changes of neuronal plasticity during development to normalize the cortical structure.

The process of embryonic/fetal brain development is highly orchestrated through main events like proliferation, differentiation, and migration of neuronal stem cells (Noctor et al., 2001; Talamillo et al., 2003; Haubensak et al., 2004; Noctor et al., 2004) and morphological and functional shaping of cortical cell populations (White and Barone 2001; Blanquie et al., 2017). Thereby, radial glia cells located at the ventricular surface develop into cortical neurons through the Pax6, Tbr2, and Tbr1 axis where the resulting cells migrate through the cortex and form the cortical inside-out layering (Englund et al., 2005; Agirman et al., 2017). The resulting number of neurons seems to be prenatally regulated through invading microglia capable of phagocytizing and controlling the number Pax6⁺ or Tbr2⁺ cells (Cunningham et al., 2013). Other suggested mechanisms include a feedback signal from cortical deep layer cells to the radial glia affecting the generation of upper layer cells as well as already occurring apoptosis of neuroprecursor cells (Blaschke et al., 1996; Toma et al., 2014). After birth, apoptosis of postmitotic neurons particularly becomes prominent in the cortex where around 50% of all neurons die (Dekkers et al., 2013; Wong and Marin

2019). This mechanism likely regulates the number of cortical neurons in an area-dependent manner through their electrical activity and indicates a specific postnatal connectivity control (Blanquie et al., 2017).

Although the short-term effects of hyperoxygenation during mid-neurogenesis of fetal mouse brain development with immediately enhanced neurogenesis particularly within cortical L5 are reported, the subsequent consequences of these phenomena during later cortical development remain enigmatic. We therefore used our established model of maternal hyperoxygenation to investigate the effects of increased oxygen tension during mid-neurogenesis (E14.5–E16.5) on later cortical development until the early postnatal state (Wagenfuhr et al., 2015). Moreover, the model allows the investigation of potential mechanisms mediating the reshape of the cortical structure during late fetal and early postnatal cortical development.

MATERIALS AND METHODS

Animals and Oxygen Treatment

C57BL/6J timed-pregnant mice were housed in their home cages within a preconditioned oxygen chamber (InerTec, Grenchen, Switzerland) at 75% oxygen or room air (21% oxygen; control condition). During the whole treatment protocol, all animals were handled by the same investigator. Fetuses of both groups showed an ordinary morphology. Pregnant mice for analysis of postnatal day 0.5 (P0.5) fetuses intraperitoneally received BrdU (50 mg/kg body weight) at E14.5, the start of hyperoxia treatment, and EdU (25 mg/kg body weight) at E17.5, 1 day after the end of the oxygen treatment. All data were gathered from randomly chosen embryos or pups from at least three independent litters per group. All animals were maintained and treated with permission of the local Department of Animal Welfare (Landesamt für Landwirtschaft, Lebensmittelsicherheit und Fischerei Mecklenburg-Vorpommern) (reference number 7221.3-1-043/16) and comply with the Tierschutzgesetz and Verordnung zur Umsetzung der Richtlinie 2010/63/EU from Germany. Of note, our study was initially designed including a hypoxia group (10% oxygen), but it was not possible to gather data for postnatal maternal hypoxia group as the mice tend to infanticide. To secure animal welfare and to be in line with German law, we had to cancel these experiments.

The brains of embryos and pups were dissected prior and immediately after oxygen treatment [E14.5 (for estimating the cortical volume) and E16.5] and postnatally at P0.5 and P3.5, fixed for 24 h in 4% paraformaldehyde (Merck, Darmstadt, Germany), and kept in 30% sucrose (Carl Roth, Karlsruhe, Germany) in PBS (Thermo Fisher Scientific, Waltham, United States). Then brains were snap-frozen, sectioned coronal at 20-μm thickness using a cryomicrotome (Leica Biosystems, Nussloch, Germany), and mounted on Superfrost Plus slides (Thermo Fisher Scientific). The slides were stored at 4°C until staining.

Immunofluorescence

Slides were washed with wash buffer (Agilent, Santa Clara, United States), and heat-induced antigen retrieval was performed using 10 mM sodium citrate (Carl Roth) with 0.05% Tween 20 (SERVA, Heidelberg, Germany) for 30 min at 95°C or 2 N HCl for 30 min at 37°C for BrdU staining. After 20 min at room temperature, slides were washed with Tris buffered saline/Tween 20 (TBST), treated with TBST containing 0.2% Triton X-100 (Carl Roth) and 10% donkey serum (Merck) for 30 min, and were incubated with primary antibodies overnight at 4°C. The following primary antibodies were used: rabbit anti-NeuN (Merck, ABN78, RRID: AB_10807945), chicken anti-NeuN (Merck, ABN91, RRID: AB_11205760), rabbit anti-cleaved-caspase-3 (CC3; Cell Signaling, 9661S, RRID: AB_2341188), mouse anti-BrdU (Thermo Fisher Scientific, B35128, RRID: AB_2536432), rabbit anti-Tbr1 (Abcam, ab31940, RRID: AB_2200219), mouse anti-Satb2 (Abcam, ab51502, RRID: AB_882455), rat anti-Ctip2 (Abcam, ab18465, RRID: AB_2064130), rabbit anti-Ctip2 (Abcam, ab28448, AB_1140055), rabbit anti-Iba1 (Wako, 019-19741, RRID: AB_839504), goat anti-Iba1 (Abcam, ab5076, RRID: AB_2224402), rabbit anti-CD68 (Abcam, ab125212, RRID: AB_10975465), rat anti-CD68 (BioRad, MCA1957GA, AB_324217), or guinea pig anti-vGlut2 (Merck, AB2251-I, RRID: AB_1587626). Subsequently, slides were incubated with corresponding secondary antibodies (Thermo Fisher Scientific), and nuclei were stained with Hoechst 33258 (Merck). For EdU analysis, slides were stained using Click-iT staining kit (Thermo Fisher Scientific) as described by the manufacturer. Finally, slides were mounted with Fluoromount-G (Biozol, Eching, Germany).

Imaging and Measurements

Most images were taken with AxioObserver Z1 with Apotome using ZEN blue 2.3 software with Tiles and Position module (all from Carl Zeiss, Oberkochen, Germany). Z-stack images of microglia-targeting Ctip2⁺ cells were taken with LSM900 with Airyscan (Carl Zeiss). Hoechst images of every sixth section with a thickness of 20 µm were taken with $\times 2.5$ objective and subsequently used for determining the volume of the whole brain and the CP corresponding to the mouse brain atlas (Allen-Institute, 2008). Thereby, we used the corpus callosum and the lateral ventricles for orientation dorsal/between the hemispheres and for lateral the piriform region and the endopiriform nucleus. For caudal sections, we used the thinner subiculum layer in the extension of hippocampal C1 layer (excluded) for dorsal orientation (**Supplementary Figure S1**). The volume was calculated by adding up the data of each slice (midpoint type) and then multiplying by 120 (every sixth slice of 20-µm thickness).

For analysis of apoptosis, fluorescence images of the whole hemispheres from the developing parietal cortex areas were taken. CC3⁺ cells were counted with ZEN blue 2.3 in the cortex from the dorsal to ventral site corresponding to the area described above. For double staining, CC3⁺ were searched as described above and imaged as Z-stack with Apotome mode. For specific marker analysis, at least four images of

the cortex were taken as Z-stack with 1-µm steps. The corresponding cells or VGlut2⁺ synapses were counted in the middle focal plane using either ZEN analysis software (Tbr1, Ctip2, and Satb2) or ImageJ (BrdU, EdU, and NeuN). L5 neurons at postnatal stages were defined by high Ctip2 expression levels as described by McKenna et al. (2011). Iba1⁺ cells and double/triple-stained cells were manually counted through the Z-stacks within the middle cortical sections in the rostro-caudal axis by the same investigator who was blinded for the treatment groups.

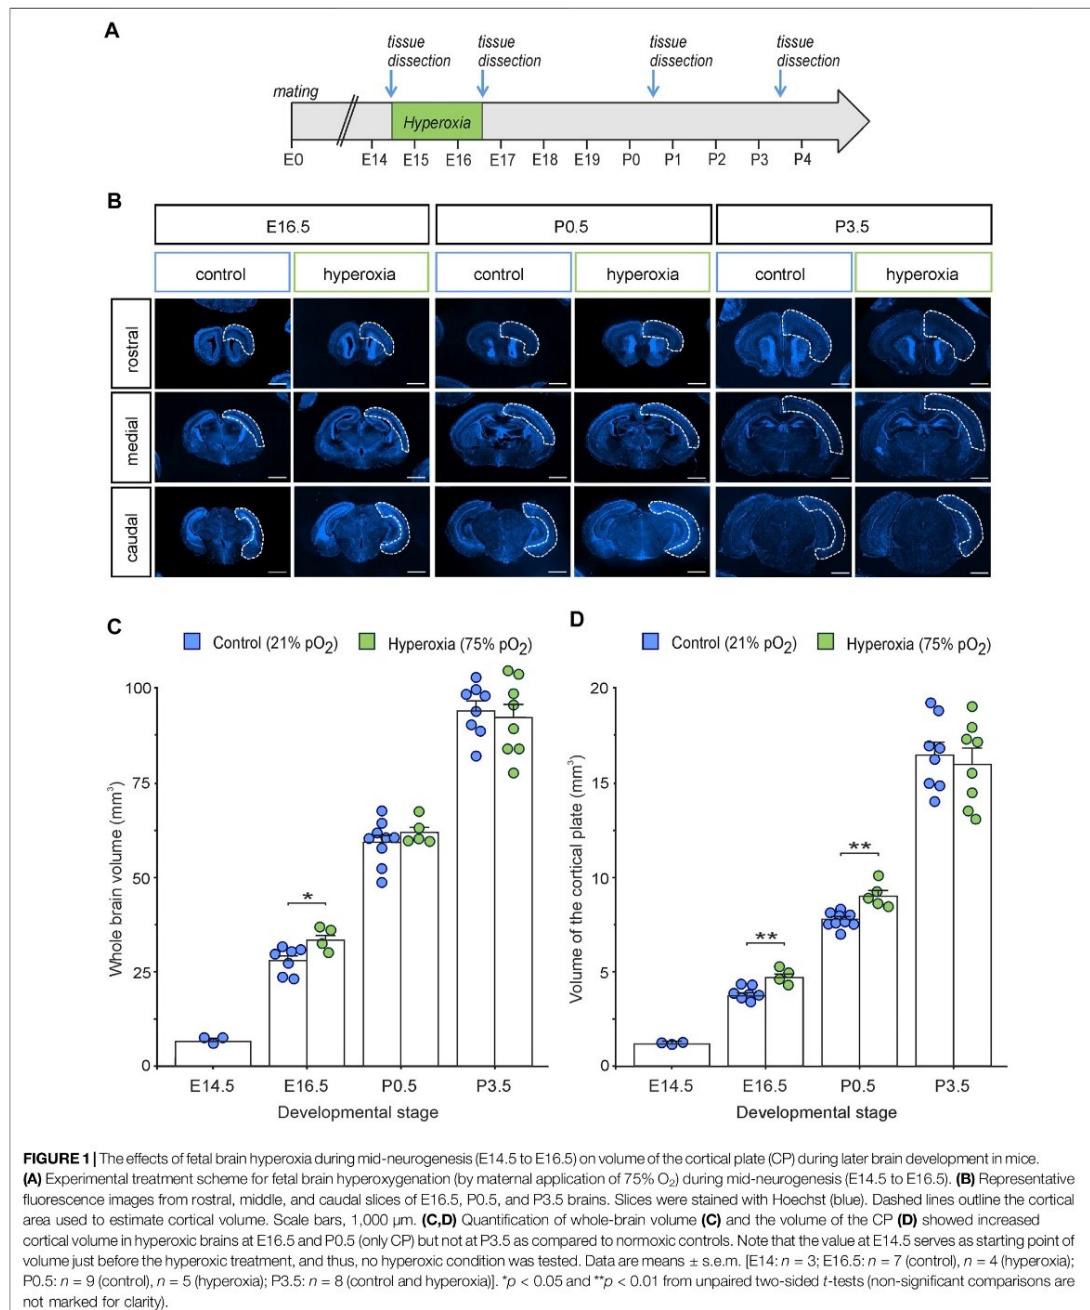

Statistics

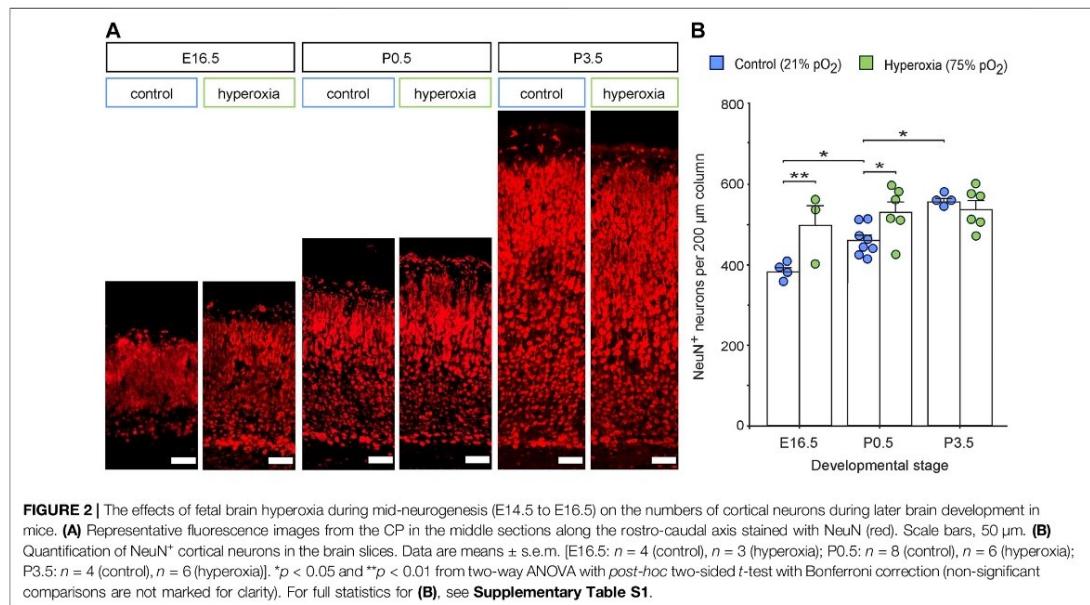

All statistical analyses were performed with RGUI 3.4.1 (R Foundation for Statistical Computing, Vienna, Austria) or SPSS version 25.0 (SPSS Inc., Chicago, IL). If not otherwise stated, statistical significance was evaluated by unpaired two-sided *t*-test or two-way ANCOVA followed by pairwise *t*-test including Bonferroni correction. Cortical volume was analyzed independent of the developmental state due to its well-known physiological large volume expansion after birth. The numbers of analyzed embryos and pups gathered from at least three independent litters are indicated by “*n*.” All data are displayed as means \pm s.e.m. with the numbers of analyzed embryos and pups indicated for each experiment. The significance level was set to $p < 0.05$ (two-tailed test).

RESULTS

Oxygen-Induced Cortical Expansion During Fetal Brain Development is Equalized at Early Postnatal Stage

To assess the time course and putative long-term persistency of the effects of oxygen tension on the rapidly changing and highly regulated fetal cortical development, we applied the already introduced mouse model of maternal hyperoxygenation known to reliably control tissue oxygen tension and subsequently neurogenesis within the developing fetal mouse brain (Wagenfuhr et al., 2015; Wagenfuhr et al., 2016). We thus applied maternal hyperoxygenation to time-pregnant mice at mid-neurogenesis from embryonic stage E14.5 to E16.5 and investigated cortical morphology during embryonic development from E14.5 to early postnatal stage at P3.5 (**Figure 1A**). The hyperoxia and control groups showed no abnormalities in their spontaneous or litter care behavior. All embryos and pups displayed normal morphology at all developmental stages examined, but the brains of the hyperoxia group appeared visually and quantitatively increased in their size at E16.5, but not on other developmental stages (**Figures 1B,C**). Indeed, mouse embryos of the hyperoxia group showed a 1.2-fold increase in the volume of the CP as compared with normoxic controls at E16.5 ($p = 0.002$), which persisted until birth (P0.5; $p = 0.015$), but not until P3.5 ($p = 0.653$; unpaired two-sided *t*-test; $n = 4–9$; **Figure 1D**).

Hyperoxygenation During Mid-Neurogenesis Accelerates But Does Not Increase Cortical Neurogenesis

To further evaluate cortical development, we used NeuN staining and analyzed the number of neurons within the middle cortical sections along the rostro-caudal axis (Figure 2). The hyperoxic embryos showed an increase of NeuN⁺ neurons per volume at E16.5 with a 1.3-fold higher neuronal density as compared with normoxic control animals (p = 0.005), which persisted until birth (P0.5) with a still 1.2-fold higher neuronal density (p = 0.013), but not until P3.5 (p = 0.581, all from *post hoc* two-sided *t*-test with Bonferroni adjustment; Figure 2B). The neuronal density in the control group rose continuously between E16.5 and P3.5, while in the hyperoxia group, the maximum neuronal density seems to be already reached at earlier developmental stages at E16.5 (Figure 2B). Of note, neuronal density in the hyperoxia group never exceeded that in the control group, indicating an accelerated but not increased cortical neurogenesis (Figure 2B).

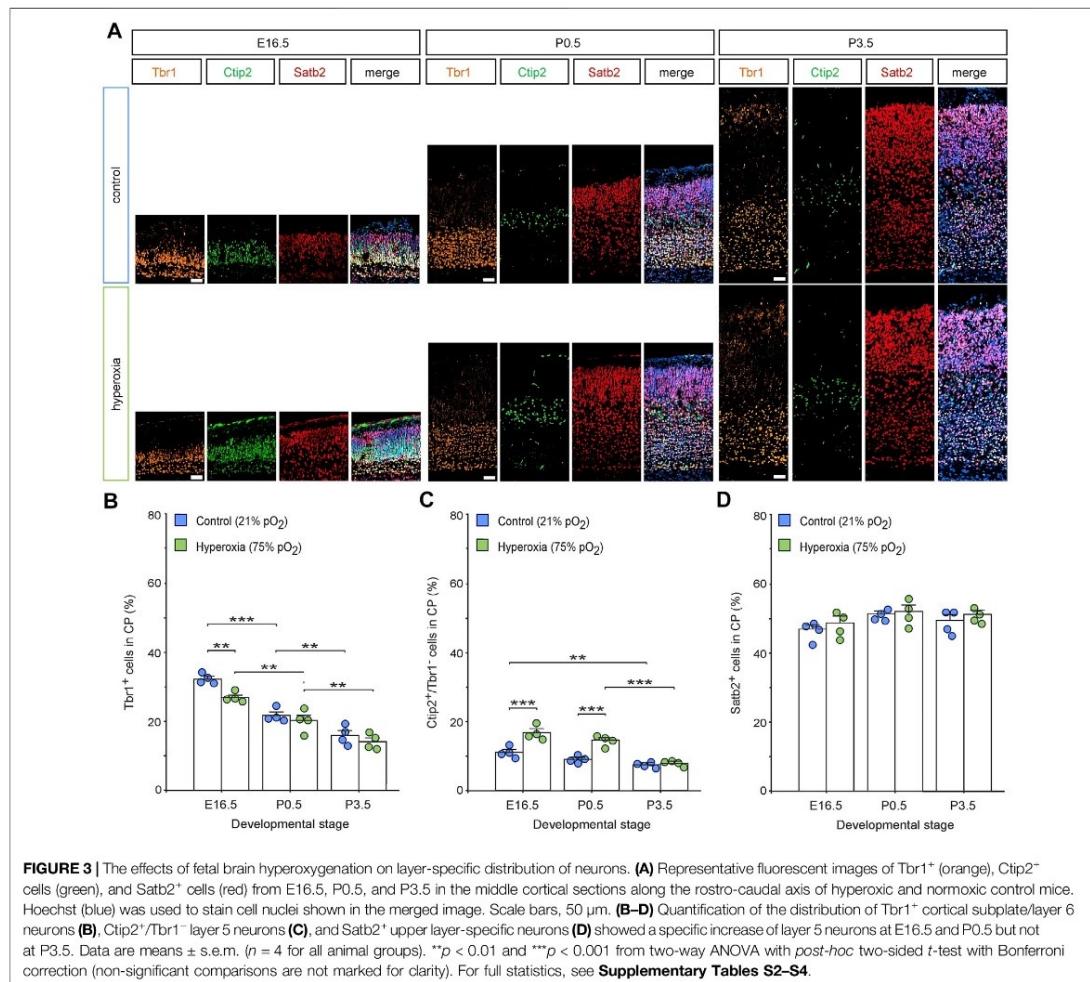

Postnatal Cortical Normalization Occurs in a Layer-Specific Manner

Whether the equalization of cortical volume and neuronal density at birth after fetal hyperoxygenation during the mid-neurogenesis phase is capable of functioning as a control mechanism for regulating neuronal layer specificity and neural circuits or whether it originates from increased raw cell numbers competitive to each other remains elusive. To shed light on this aspect, we performed a layer-specific analysis using a panel of markers Tbr1, Ctip2, and Satb2 of hyperoxic mouse

embryos and pups through the developmental stages E16.5, P0.5, and P3.5 and performed a quantitative analysis for Tbr1⁺ cells as characteristic for neurons of the SP and L6 (Hevner et al., 2001), Ctip2^{+/Tbr1⁻ cells representing L5 neurons (Arlotta et al., 2005), and Satb2⁺ cells as neurons of the upper cortical layers (Figure 3) (Britanova et al., 2008). The number of Tbr1⁺ cells in the CP decreased continuously from E16.5 to P3.5 (Figure 3B). Of note, the percentage of Tbr1⁺ cells in the CP was reduced at E16.5, although the total number of Tbr1⁺ cells was not affected (Figure 3B; Supplementary Figure S2).}

Quantification of the percentage of L5-specific neurons (Ctip2^{+/Tbr1⁻ cells; (Hevner et al., 2001; Arlotta et al., 2005) showed a persistent increase within the hyperoxic group at E16.5 (1.5-fold) and P0.5 (1.6-fold; Figure 3C), which further supports our previous data and even further demonstrates that fetal brain hyperoxia evoked persistent effects on L5 (Wagenfuhr et al., 2015). The same layer marker panel revealed no differences in the number of Ctip2⁺ cells at P3.5. Comparing the time course of Ctip2⁺ cell numbers during cortical development, there was a slow drop of the percentage of Ctip2⁺ cells within the CP between E16.5 and P3.5 in normoxic mice, but a later drop just after birth in hyperoxic mice, suggesting that the specific rearrangement of cortical L5 is postponed by hyperoxia (Figure 3C). We also found an increase in the absolute numbers of L5 neurons between E16.5 and P0.5. Since no more L5 neurons are generated at this time, we assume that this represents a change in the expression of Ctip2 rather than ongoing neurogenesis (McKenna et al., 2011; Toma et al., 2014).}

The number of upper-layer Satb2⁺ neurons was not affected by hyperoxia through all developmental stages (Figure 3D; Supplementary Figure S2).

Microglia are Involved in Postnatal Cortical Normalization After Fetal Hyperoxigenation

The postnatal regulation of the CP after fetal hyperoxigenation prompted us to evaluate the possible underlying mechanisms. There are already known mechanisms capable of controlling the number of brain cells including neurons during development (Cunningham et al., 2013; Toma et al., 2014; Blanquie et al., 2017): apoptosis known to occur during early postnatal cortical development; feedback mechanisms where the increased number of neurons signals a feedback to neuronal stem cells or microglia able to phagocytose brain cells. We consequently analyzed Iba1 staining for the number of microglia, CC3 staining as an established marker for apoptosis, and time-delayed BrdU/EdU labelling for

estimating the birthdate of the resulting neurons during brain development.

Immunohistochemical staining of Iba1⁺ cells labelling resting and activated microglia (Imai et al., 1996; Morgan et al., 2010) revealed an already visually detectable increase in microglia residing in L5 of hyperoxic P0.5 mouse pups (Figure 4A), which was not present in E16.5 or P3.5 brains (Supplementary Figure S3). Quantification of these Iba1⁺ cells revealed a specific 2.7-fold increase of microglial cells in L5 of hyperoxic mice ($p < 0.001$, *post hoc* two-sided *t*-test with Bonferroni adjustment), while the total number of Iba1⁺ cells, other layers, and developmental stages was not affected by oxygen (Figures 4B–E; Supplementary Figure S4). Microglia within the CP were predominantly found at and after P0.5, but the invasion specifically of L5 is accelerated, although not exceeding the

Postnatal Effects of Mid-Neurogenesis Hyperoxygenation

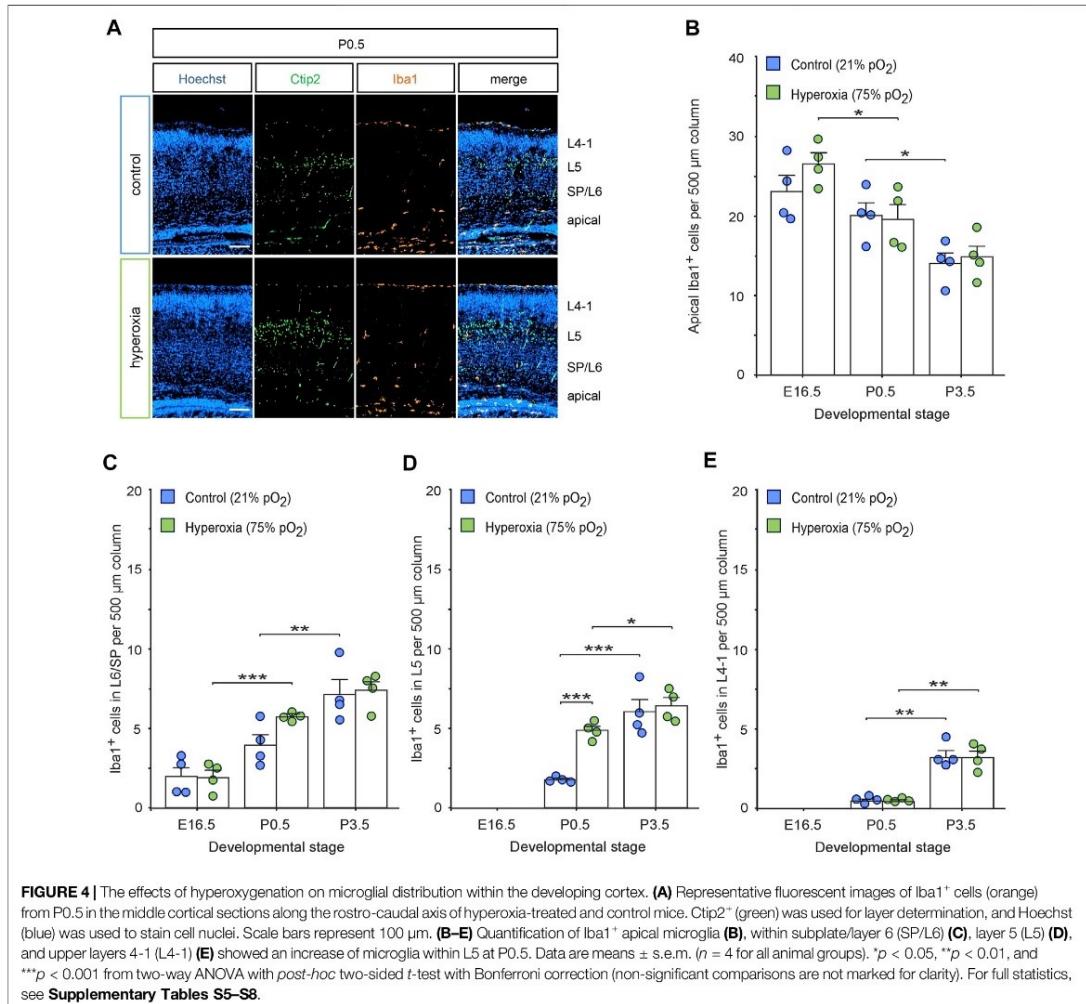

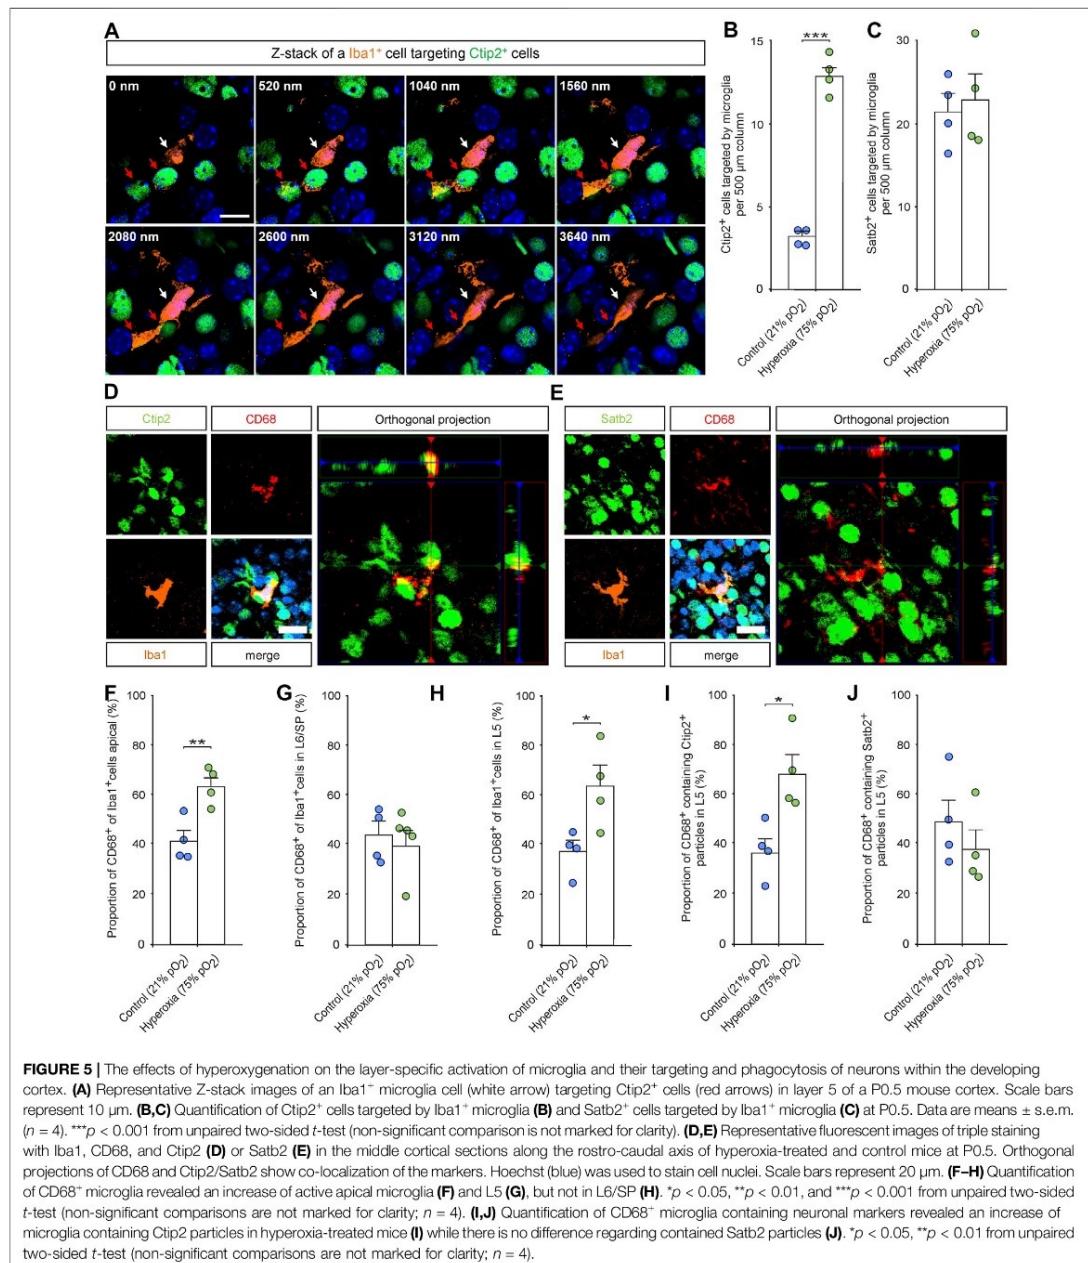

FIGURE 4 | The effects of hyperoxegenation on microglial distribution within the developing cortex. **(A)** Representative fluorescent images of Iba1⁺ cells (orange) from P0.5 in the middle cortical sections along the rostro-caudal axis of hyperoxia-treated and control mice. Ctip2⁺ (green) was used for layer determination, and Hoechst (blue) was used to stain cell nuclei. Scale bars represent 100 μ m. **(B–E)** Quantification of Iba1⁺ apical microglia **(B)**, within subplate/layer 6 (SP/L6) **(C)**, layer 5 (L5) **(D)**, and upper layers 4-1 (L4-1) **(E)** showed an increase of microglia within L5 at P0.5. Data are means \pm s.e.m. ($n = 4$ for all animal groups). * $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$ from two-way ANOVA with post-hoc two-sided t-test with Bonferroni correction (non-significant comparisons are not marked for clarity). For full statistics, see Supplementary Tables S5–S8.

number of microglia at P3.5. This is further supported by analysis of the apical and SP/L6 microglia, where the decrease of apical microglia and the successive increase of SP/L6 occurred between P0.5 and P3.5 in normoxic control mice, but already occurred between E16.5 and P0.5 in hyperoxic mice (the increase in Iba1⁺ microglia in SP/L6 at P0.5 represents only a non-significant trend). Intriguingly, we could show that microglia in L5-targeted Ctip2⁺ cells without morphological signs of apoptosis (**Figure 5A**). An analysis of Ctip2⁺ and Satb2⁺ cells targeted by microglia at time point P0.5 showed that Ctip2⁺ cells were targeted by microglia significantly more often in the hyperoxia group than in the control group (**Figure 5B**). At the same time, there was no difference in the number of Satb2⁺ cells targeted by microglia (**Figure 5C**; **Supplementary Figure S5**). We

consequently analyzed the number of active microglia by using the combination of Iba1 and the microglia activation marker CD68 (Rabinowitz and Gordon 1991; Imai et al., 1996; Morgan et al., 2010; Jurga et al., 2020). Quantification revealed that there are indeed more active microglia in L5 and also apical, but not between these in L6/SP (**Figures 5D–H**). Further analyses revealed Ctip2⁺ and Satb2⁺ particles in these active microglia in L5, but—interestingly—only the number of active microglia containing Ctip2⁺ particles was increased in hyperoxic as compared to control brains (**Figure 5I,J**).

To further evaluate whether adaptive mechanisms contribute to normalization of the number of neurons cortex after fetal hyperoxegenation, we performed a birth-dating analysis using BrdU application immediately before and EdU application 1 day

after oxygen treatment and subsequent histological analyses of BrdU/EdU incorporation by cortical cells at P0.5 (see Figure 6A for experimental paradigm). Immunostaining of both markers showed that a large proportion of CP neurons were generated at

E14.5 (BrdU⁺), while cells generated at E17.5 (EdU⁺) represent a much smaller part of the developing cortex (Figures 6B,C). Quantification of BrdU⁺/EdU⁺ cells in the CP revealed a significantly 1.4-fold increase in the number of BrdU⁺ cells

Ergebnisse

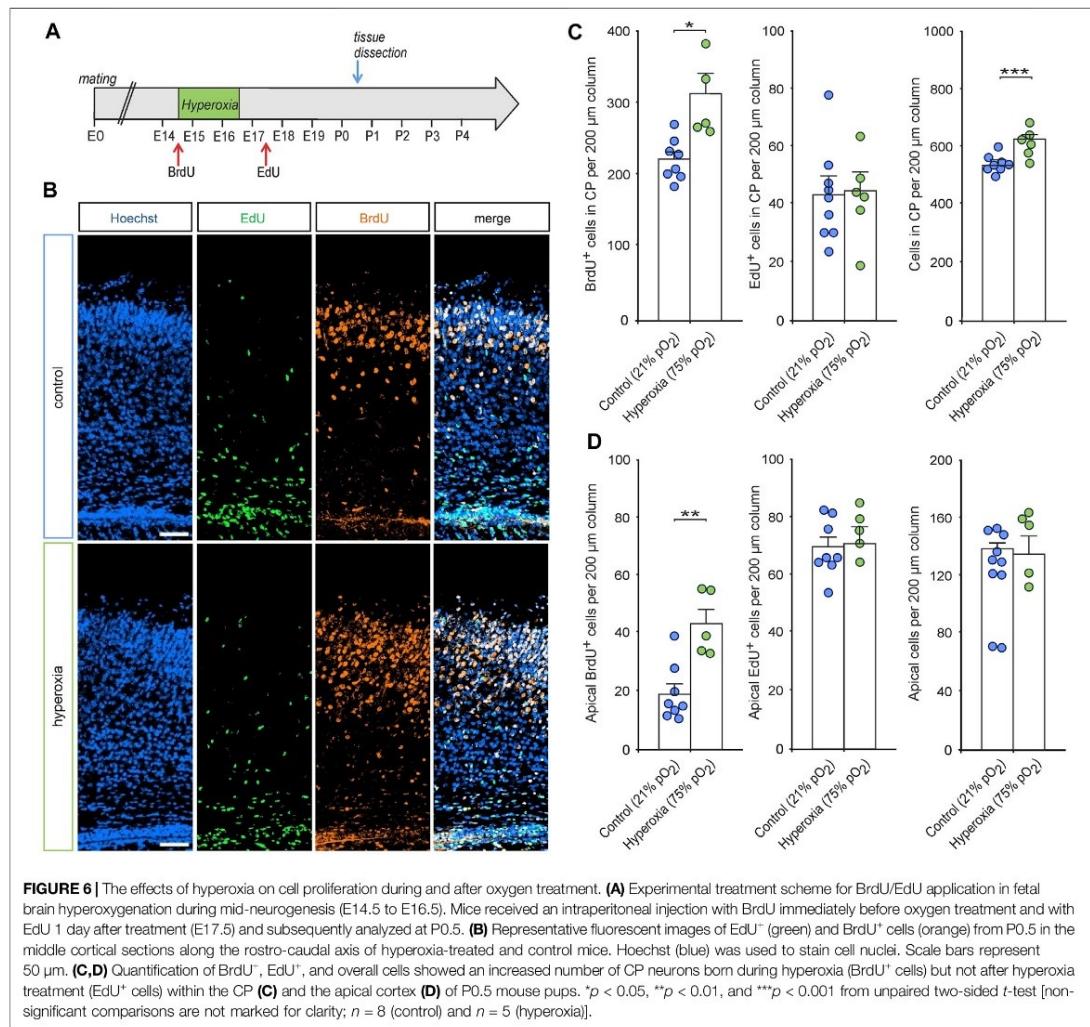

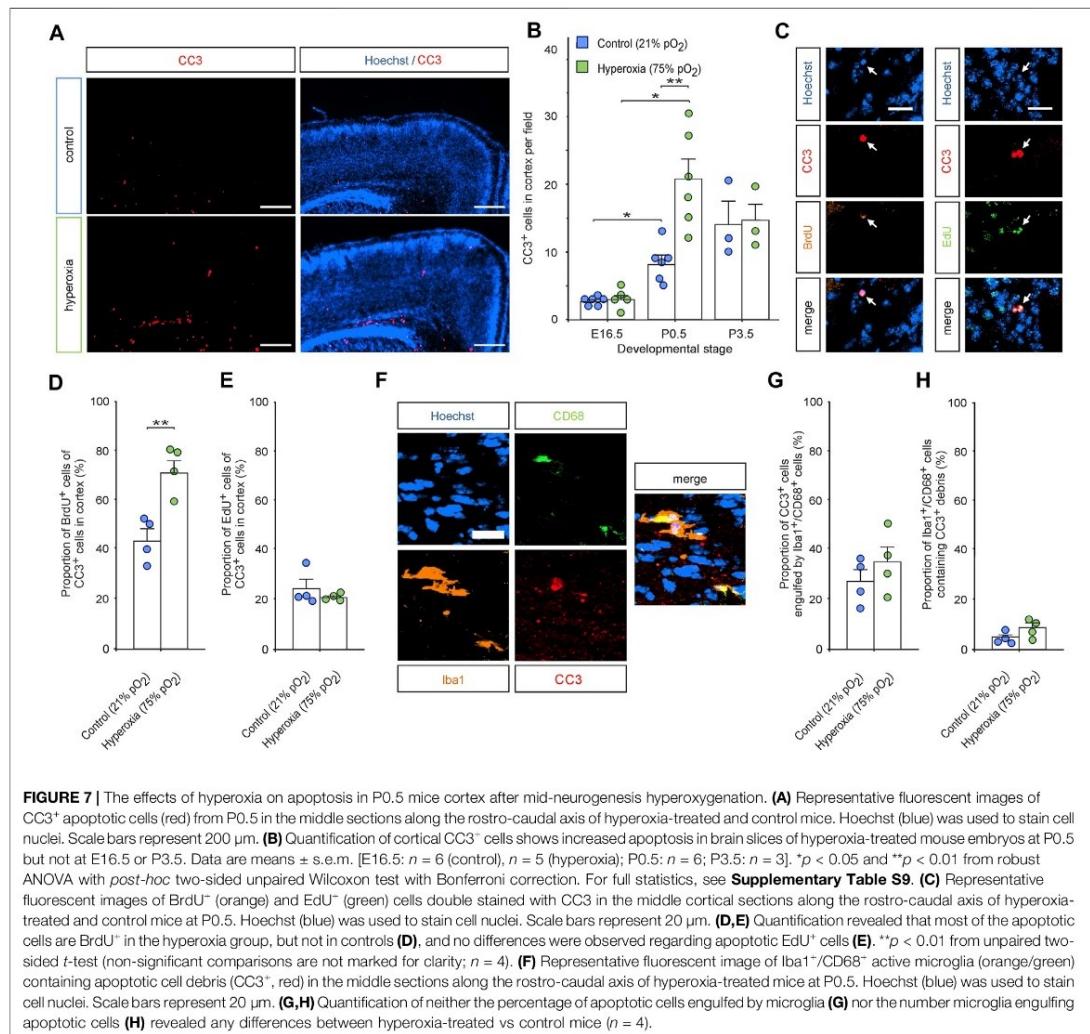

FIGURE 6 | The effects of hyperoxia on cell proliferation during and after oxygen treatment. **(A)** Experimental treatment scheme for BrdU/EdU application in fetal brain hyperoxigenation during mid-neurogenesis (E14.5 to E16.5). Mice received an intraperitoneal injection with BrdU immediately before oxygen treatment and with EdU 1 day after treatment (E17.5) and subsequently analyzed at P0.5. **(B)** Representative fluorescent images of EdU⁺ (green) and BrdU⁺ cells (orange) from P0.5 in the middle cortical sections along the rostro-caudal axis of hyperoxic-treated and control mice. Hoechst (blue) was used to stain cell nuclei. Scale bars represent 50 µm. **(C,D)** Quantification of BrdU⁺, EdU⁺, and overall cells showed an increased number of CP neurons born during hyperoxia (BrdU⁺ cells) but not after hyperoxia treatment (EdU⁺ cells) within the CP **(C)** and the apical cortex **(D)** of P0.5 mouse pups. * $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$ from unpaired two-sided *t*-test [non-significant comparisons are not marked for clarity; $n = 8$ (control) and $n = 5$ (hyperoxia)].

($p = 0.021$) in response to hyperoxia, but not of EdU⁺ cells ($p = 0.886$, both from unpaired two-sided *t*-test), as a putative later feedback reaction. Thereby, the increased rate of BrdU⁺ cells led to an increase of the overall cells in the CP. Notably, there were more BrdU⁺ cells left at the apical side of the cortex ($p = 0.002$), but again, no change in EdU⁺ cells ($p = 0.791$, both from unpaired two-sided *t*-test; **Figure 6D**).

We further analyzed CC3⁺ apoptotic cells within the middle cortical sections along the rostro-caudal axis showing increased apoptosis in hyperoxic P0.5 mouse pups. Immunostaining with quantification showed that the overall number of CC3⁺ cells in the hyperoxic group is increased by 2.6-fold with apoptosis predominantly occurring in the apical regions (**Figures 7A,B**). We then evaluated whether layer 5 cells of the cortex were

apoptotic through double labelling of CC3⁺ and Ctip2⁺, but there was almost no cell possessing both markers (<0.1% of Ctip2⁺ cells). Since apoptosis occurred mainly apical where increased proliferation could be detected in the hyperoxia group at E14.5, we analyzed the number of BrdU⁺/CC3⁺ and EdU⁺/CC3⁺ cells (**Figures 7C–E**). Quantification revealed that indeed apical BrdU⁺ cells were more often apoptotic while EdU⁺ cells were not. Since apical active microglia were detected more often in the hyperoxia group, we finally investigated whether there are changes in elimination of apoptotic cells by Iba1⁺/CD68⁺ active microglia. However, we have neither found any increase in the number of active microglia-targeting CC3⁺ cells nor in the number of apoptotic cells that were engulfed by microglia in hyperoxic brain when compared to controls (**Figures 7F–H**).

Number of Excitatory Synapses Follows Normalization in L5

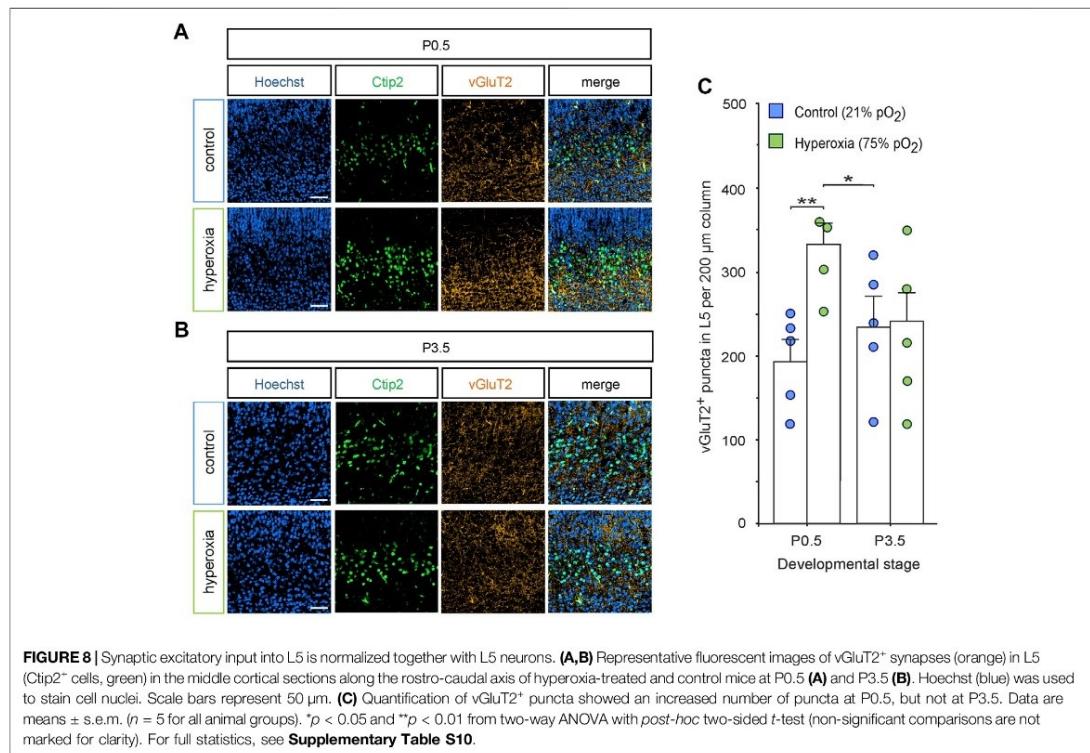

To provide first data on the effects on mid-neurogenesis hyperoxigenation on synaptic development, we analyzed the expression of the vesicular glutamate transporter 2 (vGlut2) as a common target for microglia pruning in later stages and a marker for the predominant form of excitatory synapses during early brain development (Nakamura et al., 2007; Schafer et al., 2012) (Figure 8). Double staining of vGlut2 and Ctip2 showed increased synaptic input into L5 in the hyperoxia animal group at P0.5: quantification in L5 showed that there were 1.7-fold more vGlut2⁺ puncta in the hyperoxia group as compared with

normoxic controls at P0.5 ($p = 0.006$), which did not persist until P3.5 (Figure 8C). Additionally, the number of vGlut2⁺ puncta in L5 in the hyperoxia group at P0.5 temporary overshoots that of controls at P0.5 and P3.5 ($p = 0.033$).

DISCUSSION

We present here that the short-term effects of hyperoxigenation during mid-neurogenesis of fetal mouse brain development (E14.5 to E16.5) with increased neuroprecursor cell proliferation within the SVZ/OSVZ (Wagenfuhr et al., 2015) translate into an accelerated cortical development but without

Ergebnisse

increase in cortical neurogenesis and cortical volume at early postnatal stage. Indeed, the CP is expanded through a specific overshoot amount of Ctip2⁺/Tbr1⁻ L5 neurons in later fetal development until birth in hyperoxic mouse cortex, which is normalized at early postnatal stage. This normalization is accompanied by an increase of microglial cells within L5 capable of targeting the respective neurons but no signs of L5 neuronal apoptosis.

We used our established model of maternal hyperoxigenation to investigate the effects of increased fetal brain oxygen tension during mid-neurogenesis (E14.5–E16.5) on later cortical development until the early postnatal state (Wagenfuhr et al., 2015; Wagenfuhr et al., 2016). Early chronic hyperoxigenation in this model causes severe reduction of neuroprecursor cell proliferation and the apical neuroprecursor cell pool (Markert et al., 2020). Contributing to this, Lange et al. (2016) reported that early hyperoxigenation from E10.5 to E13.5 is able to alter neuroprogenitor cell fate leading to a decrease of expanding neuroprogenitors. However, late or postnatal hyperoxigenation is known to cause brain damage accompanied by excessive loss of neurons (Gerstner et al., 2008; Yis et al., 2008; Tuzun et al., 2012), while short-term hyperoxigenation during mid-neurogenesis of fetal mouse brain development (E14.5 to E16.5) leads to an immediate expansion of a distinct proliferative cell population basal of the SVZ, which subsequently contributes to

corticogenesis by heading for deeper cortical layers (Wagenfuhr et al., 2015). Finally, the amount of Ctip2⁺ neurons in L5 projecting into various brain regions is markedly overshot after short-term maternal hyperoxigenation and at birth with a normalization until early postnatal stage (Hattox and Nelson 2007; Oswald et al., 2013; Wagenfuhr et al., 2015). Oxygen levels are known to directly regulate neuroprecursor cell maintenance, proliferation, and differentiation *in vitro* through the activation of several oxygen-sensitive signaling pathways (Chen et al., 2007; Pistollato et al., 2007; Giese et al., 2010; Mazumdar et al., 2010; Braunschweig et al., 2015; Mennen et al., 2020). Although the *in vitro* cell models are not directly comparable to our *in vivo* system, analyses of the fetal brain oxygen tension revealed that maternal hyperoxigenation of 75% leads to an increase of oxygen tension in the neurogenic niche of the VZ/SVZ from below 1.1% in maternal normoxic condition to oxygen levels above this threshold in hyperoxic animals, which is also supported by other colleagues (Wagenfuhr et al., 2015; Lange et al., 2016). Of note, there are no *in vivo* oxygen markers available for small laboratory animals to detect changes in oxygen levels in the range of 5%–20% to further define the tissue oxygen tension in the hyperoxic condition. However, maternal hyperoxia is unlikely to cause oxygen levels towards 20%, which is the commonly used oxygen tension in cell culture

experiments. Thus, the higher oxygen tension in hyperoxic brain tissue likely represents the *in vitro* condition of mild hyperoxia and provides a stimulating environment for maintenance and proliferation of neuroprecursor cells as demonstrated in cell culture (Chen et al., 2007; Chen et al., 2010; Santilli et al., 2010; Braunschweig et al., 2015; Qi et al., 2017) when compared to very low oxygen conditions.

The observed normalization of the brain morphology in the early postnatal stage indicates that the brain is able to compensate prenatally evoked morphological changes at least for an excess of cell population. Within the period of synaptogenesis during the first 30 postnatal days, neuronal programmed cell death or apoptosis is known to play a major role in shaping the neocortex with a peak around P5 in rodents in most studies (Southwell et al., 2012; Ahern et al., 2013; Blanquie et al., 2017). In the six-layered isocortex, the loss of neuronal density displays a layer-specific pattern and manifested itself mostly in L2–L4, whereas L1, L5, and L6 show fewer changes. We thus studied whether this physiological process is also mediating the normalization neuronal cell counts in L5 of hyperoxic mouse cortex in earlier postnatal stages by using CC3 staining (Fernandes-Alnemri et al., 1994; Nicholson et al., 1995; Wong et al., 2018). Surprisingly, almost none of L5 Ctip2⁺ neurons showed CC3 marker expression, indicating that apoptosis is not involved in controlling the number of L5 neurons after mid-neurogenesis hyperoxygenation. The rare occurrence of apoptosis in L5 in the first days after birth is however in line with previous systematic studies of layer-specific postnatal apoptosis (Verney et al., 2000; Denaxa et al., 2018). However, we found an increase in the number of CC3⁺ apoptotic cells in hyperoxic as compared to normoxic brain at P0.5, but their location was vastly limited to the apical proliferative zone outside the CP, and they were eliminated by active microglia. This phenomenon might be interpreted as an adaptive response of the physiological apical apoptosis at birth to the hyperoxia-induced increased proliferation of precursor cells at E14.5 and at the end of mid-neurogenesis phase at E16.5 (White and Barone 2001; Wagenfuhr et al., 2015). Putative feedback mechanisms regulating neuroprecursor cell proliferation such as activity-dependent negative feedback from developing neurons (Toma et al., 2014) might be involved in cortical re-shaping after mid-neurogenesis hyperoxygenation. We thus applied the thymidine analogue EdU at a time point when it is known that the brain enlarges (E17.5) and 1 day after the oxygen treatment and analyzed EdU uptake at birth (P0.5). Although hyperoxygenation provokes strong immediate effects on the number of CP neurons born at E14.5 as described earlier (Wagenfuhr et al., 2015), cells generated after the hyperoxygenation phase at E17.5 predominantly reside on the apical side of the developing cortex and do not yet contribute to CP morphology at birth. Moreover, there is no indication for an adaption regarding the number of neurons in the CP during the post-hyperoxygenation phase.

Microglia already physiologically colonize the developing brain at E10.5 where they regulate the number of precursor

cells through phagocytosis (Cunningham et al., 2013; Arnò et al., 2014; Tronnes et al., 2016). Until E16.5, microglia exclusively reside within the proliferating zones while they start to invade into the CP as late as during the early postnatal stage (Squarzoni et al., 2014). The majority of microglia in the developing cerebral cortex have an activated morphology and express markers associated with activation, and functional studies revealed that microglia regulate neuroprecursor cell number in the developing cortex by phagocytosis (Cunningham et al., 2013). Interestingly, most precursor cells targeted by Iba1⁺ microglia in the cortical proliferative zones did not show signs of cell death or apoptosis (Fricker et al., 2012; Cunningham et al., 2013). Our data suggest a very similar mechanism during the re-shaping of the cortical layers after mid-neurogenesis hyperoxygenation: increased numbers of Iba1⁺ microglia, which also express CD68 as a marker for active microglia (Rabinowitz and Gordon 1991; Jurga et al., 2020), target and incorporate Ctip2⁺ L5 neurons with no apoptotic signs at the critical stage P0.5. However, the number of targeted Satb2⁺ cells or incorporated Satb2⁺ particles at the same time remains unaffected, suggesting a specific effect on Ctip2⁺ L5 neurons. Nevertheless, our study is limited to immunohistochemical staining and cannot exclude other effects such as a critical change in microglial support for surviving of L5 cells (Ueno et al., 2013). In addition, the study is limited to a rather small sample size. Non-significant trends like the increased number of microglia in SP/L6 at E16.5 could potentially be relevant. Since there are no changes in microglial activity or absolute L6-specific Tbr1⁺ neurons, this may reflect an accelerated invasion of the cortical plate where microglia migrate from apical through SP and L6 to L5 (Swinnen et al., 2013). Consequently, future functional studies with activation and depletion of microglia during late prenatal and early postnatal cortical development are warranted to investigate the exact microglia–L5 neuron interactions in cortical re-shaping after critical insults during mid-neurogenesis such as hyperoxygenation. These data in conjunction with no indications for changes in cell migration [data on cortical layering herein and Wagenfuhr et al., (2015)] or compensatory reduction or shift of precursor proliferation strongly suggest different mechanisms to normalize the overshoot amount of neuroprecursor cells depending on the brain region with CC3-mediated apoptosis as one major mechanism within the apical proliferative zone (VZ/SVZ) and microglia playing a key role in cortical L5.

To first shed light on alterations of early synaptic connectivity within the developing cortex by mid-neurogenesis hyperoxygenation, we further analyzed the expression of vGluT2 as a common marker for the predominant form of excitatory synapses during early brain development (Nakamura et al., 2007). We detected a temporary overshoot of glutamatergic synaptic input into L5 in the hyperoxia animal group at P0.5 with normalization until P3.5 in fairly accurate parallelism to the changes in cortical L5 neurogenesis. Although the underlying mechanisms of this normalization need to be determined by functional studies as outlined above, it might also be mediated through activated microglia, because microglia

have been reported to have a pivotal role in remodeling of developing synapses in the early postnatal brain (Schafer et al., 2012). To determine whether the morphological changes in response to hyperoxygenation during mid-neurogenesis translate into behavioral disruption, early postnatal behavioral testing of the pups using righting reflex test, gait analysis, and negative geotaxis test (Lubics et al., 2005; Fan et al., 2008) is urgently required in future studies. Our observations might then be of interest for investigating layer 5-specific neurodevelopmental disorders (Kolomeets and Uranova 2019; Mi et al., 2019) and their potential therapeutic/prophylactic interventions.

Together, the present data demonstrate that fetal brain hyperoxygenation during mid-neurogenesis from embryonic stage E14.5 to E16.5 accelerates cortical development in the fetal mouse brain. The cortical CP is expanded through a specific overshoot amount of L5 neurons at E16.5 and at birth in hyperoxic mouse cortex, which is subsequently normalized at early postnatal stage. This normalization is accompanied by an increase of microglial cells within L5 capable of targeting and incorporating the respective neurons with no signs of L5 neuronal apoptosis. Indeed, our data strongly suggest different mechanisms to the overshoot number of neuroprogenitor cells depending on the brain region with CC3-mediated apoptosis as the mechanism within the apical proliferative zone and microglial targeting in cortical L5. However, future functional studies on microglia using ablation and/or stimulation of microglia are warranted to finally confirm that an increased microgliosis in L5 is responsible or at least contribute to postnatal adaption to prenatal hyperoxia effects on corticogenesis.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusion of this article will be made available by the authors, without undue reservation.

Ergebnisse

Supplementary Figure S1. Example for the determination of the volume of the cortical plate (CP). Every 6th Hoechst stained slice of a mouse brain was outlined as shown in the figure (left to right: rostral, middle and caudal section) and used to calculate the volume. Scale bar, 1000 µm.

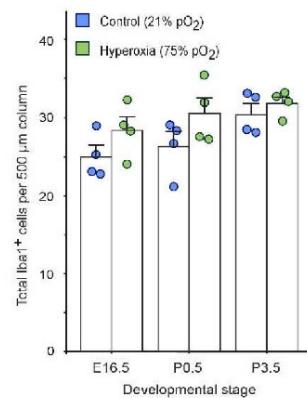

Supplementary Figure S2. Effects of maternal hyperoxygenation on the absolute number of layer specific neurons. Quantification of absolute Tbr1⁺, Ctip2⁺/Tbr1⁻ and Satb2⁺ cells within 250 µm wide cortical columns of E16.5, P0.5 and P3.5 mice. Data are means±s.e.m. (n = 4). * p<0.05, ** p<0.01, *** p<0.001 from two-way ANOVA with *post-hoc* two-sided t-test with Bonferroni correction. For full statistics, see **Supplementary Tables S11-S13**.

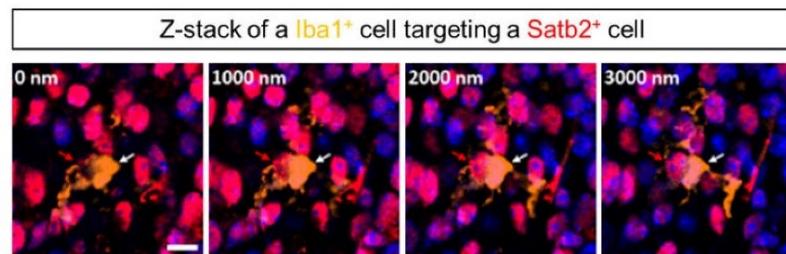

Supplementary Figure S3: Effects of fetal brain hyperoxygenation on the distribution of microglia in E16.5 and P3.5 mouse cortex. Representative fluorescent images of $\text{Iba}1^+$ cells (orange) from **(a)** E16.5 and **(b)** P3.5 in the middle cortical sections along the rostro-caudal axis—of hyperoxia treated and control mice showed no differences. $\text{Ctip}2^+$ (green) was used for layer determination and Hoechst (blue) was used to stain cell nuclei. Scale bars represent 100 μm .

Ergebnisse

Supplementary Figure S4. Effects of hyperoxygenation on the total number of microglia within the developing cortex. Quantification of the total number of Iba1⁺ microglia showed no differences with respect to hyperoxia treatment. Data are means \pm s.e.m. ($n = 4$). * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$ from two-way ANOVA with *post-hoc* two-sided t-test with Bonferroni correction. For full statistics, see **Supplementary Table S14**.

Supplementary Figure S5. Iba1⁺ cells are able to target Satb2⁺ cells. Representative z-stack images of a microglia cell (white arrow) targeting Satb2⁺ cells (red arrow) in a P0.5 mouse cortex. Scale bars represent 10 μ m.

4.2 Early Chronic Intermittent Maternal Hyperoxygenation Impairs Cortical Development by Inhibition of Pax6-Positive Apical Progenitor Cell Proliferation

Franz Markert, Luisa Müller, Kathrin Badstübner-Meeske & Alexander Storch

Journal of Neuropathology & Experimental Neurology, 2020, Band 79, Nummer 11,
Seiten 1223 - 1232

Zusammenfassung:

Im Hinblick auf den proliferationssteigernden Effekt einer maternalen Sauerstoffbehandlung bei Mäusen von Embryonalstadium (E)14,5 bis E16,5 wurde in dieser Studie untersucht, inwieweit sich eine chronische Behandlung mit Sauerstoff auf die kortikale Entwicklung auswirkt. Dazu wurden trächtige C57BL/6J Mäuse intermittierend in 75% Sauerstoff gehalten und die Feten zum E16,5 mittels Immunhistochemie auf neuronale Proliferations- und Differenzierungsmarker hin untersucht. Die chronische Sauerstoffbehandlung führt zu einer Verringerung der Anzahl an neuronalen Vorläuferzellen und einer Reduktion von mitotischen Zellen in den betroffenen Kortizes. Diese Veränderungen resultieren in einer abnormalen kortikalen Schichtung, sodass mehr Tbr1⁺-Neurone der inneren Schicht des Kortex, dafür weniger Satb2⁺-Neurone der äußeren Schichten zu finden sind. Passend dazu wird eine verringerte Expression des neuronalen Markers NeuN in den oberen kortikalen Schichten festgestellt. Die Ergebnisse zeigen, dass eine zeitige chronisch intermittierende Sauerstoffbehandlung, im Gegensatz zur kurzzeitigen Sauerstoffbehandlung, zu verringrigerter Proliferation neuronaler Stammzellen und einer veränderten kortikalen Schichtung führt. Die Applikationsdauer sowie der Zeitpunkt der Applikation einer Sauerstoffbehandlung scheinen daher maßgeblich den Effekt auf die kortikale Entwicklung zu beeinflussen. Zur Aufklärung der zugrundeliegenden Mechanismen, sowie der Frage inwieweit diese Veränderungen persistieren, sind weitere Folgestudien in Form von Zellzyklusanalysen, neuronalen Migrationsanalysen sowie Verhaltensanalysen notwendig.

Early Chronic Intermittent Maternal Hyperoxygenation Impairs Cortical Development by Inhibition of Pax6-Positive Apical Progenitor Cell Proliferation

Franz Markert, MSc, Luisa Müller, MSc, Kathrin Badstübner-Meeske, PhD, and Alexander Storch , MD

Abstract

Maternal hyperoxygenation is a feasible, noninvasive method to treat fetal diseases, such as heart hypoplasia, but effects of maternal hyperoxygenation on the developing brain remain poorly understood. Previous studies showed that short-term maternal hyperoxygenation during midneurogenic phase (E14–E16) but not in earlier development (E10–E12) increases oxygen tension and enhances neurogenesis in the developing mouse cortex. We investigated effects of early chronic maternal hyperoxygenation (CMH) as a potential clinical treatment. Pregnant C57BL/6J mice were housed in a chamber at 75% atmospheric oxygen and the brains of E16 fetuses were analyzed using immunohistochemistry. The mitosis marker phH3 showed a significant reduction of proliferation in the dorsolateral cortices of CMH-treated E16 fetuses. Numbers of Tbr2-positive intermediate progenitor cells were unaffected whereas numbers of Pax6-positive apical progenitor cells were significantly reduced in CMH-treated mice. This resulted in altered cortical plate development with fewer Sath2-positive upper layer neurons but more Tbr1-positive neurons corresponding to the deeper layer 6. Thus, maternal hyperoxygenation affects the developing cortex depending on timing and length of applied oxygen. Early CMH causes a severe reduction of neuroprogenitor proliferation likely affecting cortical development. Further studies are needed to investigate the mechanisms underlying these findings and to assess the clinical and neurodevelopmental outcomes of the pups.

Key Words: Corticogenesis, Hyperoxia, Maternal hyperoxygenation, Neural stem cells, Oxygen tension.

INTRODUCTION

Ventilation therapy in respiratory or lung diseases is standard of care in humans of all ages and oxygen therapy is often necessary in newborns, particularly for the survival of premature infants (1–3). On the other hand, oxygen therapy to specifically change tissue oxygen tension is rarely used in evidence-based medicine. Currently, there is interest in maternal hyperoxygenation for influencing fetal development, mainly for heart hypoplasia (4–6). Indeed, maternal hyperoxygenation affects fetal pulmonary blood flow and oxygen saturation and eventually heart hypoplasia (7–9). While most of the available clinical studies address short-term protocols, a few trials address the effects of long-term protocols (10). However, besides the potential effects of oxygenation on congenital heart diseases, experimental evidence shows that oxygen is an important signaling molecule in neural development. Specifically, various research groups reported that neural progenitor cells reside in a hypoxic niche in both embryonic and adult brain (11–13), and numerous in vitro data regarding oxygen tension have revealed oxygen as a key factor for proliferation and differentiation of rodent and human neural stem and progenitor cells (14–19). In contrast, only very few studies systematically investigated the effects of various oxygen tensions in brain tissue by maternal hyperoxygenation or altering angiogenesis and confirmed that altered oxygen conditions affect the developing brain *in vivo* by regulating the balance between neural stem cell maintenance and their differentiation (12, 20, 21).

As the available data from *in vivo* studies addressed only the effects of short-term maternal hyperoxygenation resulting in increased neurogenesis during cortical development, the effects of chronic maternal hyperoxygenation (CMH) are poorly understood. Contrary to short-term maternal hyperoxygenation, a recent pilot study in humans showed that CMH impairs fetal neuronal development resulting in reduced head growth of infants, although no alterations in neurodevelopmental assessments were observed (22). These observations raise the question whether CMH protocols have different effects on brain development as compared with short-term protocols. We thus investigated the effects of an intense CMH on neural development, including the neural stem cell expansion phase. We used pregnant C57BL/6J mice as a

model known to be susceptible to increased fetal brain oxygen tension, particularly within the stem cells niches of the developing brain, after treatment of the mother animals with 75% atmospheric oxygen (21).

MATERIALS AND METHODS

Animals and Oxygen Treatment

For oxygen treatment, C57BL/6J timed-pregnant mice were housed in their home-cages within an oxygen-chamber (InerTec, Grenchen, Switzerland) with a probe for oxygen. Further, for CMH mice were treated from E5 to E16 with cycles of 75% oxygen for one day followed by one day at room air (Fig. 1A). This intermittent treatment scheme was necessary since hyperoxygenation lasting longer than 48 hours affects the health of adult mice (12). Control mice were kept in room air straight next to the oxygen chamber ensuring the same environmental conditions besides oxygenation. All animals were handled by the same investigator during the entire treatment protocol. The fetuses in both groups showed an ordinary morphology with ~7 fetuses per litter. All data were gathered from randomly chosen fetuses from at least 3 independent litters per group. All animals were maintained and treated with permission of the local Department of Animal Welfare (Landesamt für Landwirtschaft, Lebensmittelsicherheit und Fischerei Mecklenburg-Vorpommern) and comply with the Tierschutzgesetz and Verordnung zur Umsetzung der Richtlinie 2010/63/EU from Germany.

Immediately after oxygen exposure, the embryonic brains were dissected, fixed for 24 hours in 4% paraformaldehyde (Merck, Darmstadt, Germany) and kept in 30% sucrose (Carl Roth, Karlsruhe, Germany) in Dulbecco's Phosphate-Buffered Saline (Thermo Fisher Scientific, Waltham, MA). Then brains were snap-frozen, sectioned coronal at 20 µm thickness with microtome (Leica Biosystems, Nussloch, Germany) and mounted on Superfrost Plus slides (Thermo Fisher Scientific). The slides were stored at 4°C until staining.

Immunofluorescence

Slides were washed with TBST Wash Buffer (Agilent, Santa Clara, CA) and heat-induced antigen retrieval was performed using citrate buffer containing 10 mM sodium citrate (Carl Roth) and 0.05% Tween 20 (SERVA, Heidelberg, Germany) for 30 minutes at 95°C. After 20 minutes at room temperature, slides were washed with TBST and treated with TBST containing 0.2% Triton X-100 (Carl Roth) and 10% donkey serum (Merck) for 30 minutes. Next, slides were incubated with Isolectin IB4 (Thermo Fisher Scientific) or primary antibodies overnight at 4°C. The following primary antibodies were used: Mouse anti-phospho-histone H3 (phH3; Cell Signaling, Danvers, MA; 9706, 1:100); mouse anti-Satb2 (Abcam, Cambridge, UK; ab51502, 1:500); rabbit anti-cleaved-caspase-3 (Cell Signaling; 9661S; 1:200); rabbit anti-NeuN (Merck; ABN78, 1:600); rabbit anti-Pax6 (Covance, San Diego, CA; PRB-278P, 1:300); rabbit anti-Tbr1 (Abcam; ab31940, 1:250); rabbit anti-Tbr2 (Abcam; ab183991, 1:600); and rat anti-Ctip2 (Abcam; ab18465, 1:500).

1224

Subsequently, slides were incubated with corresponding secondary antibodies (Thermo Fisher Scientific) and nuclei were stained with Hoechst 33258 (Merck). To preserve immunofluorescence, slides were mounted with Prolong Antifade Diamond (Thermo Fisher Scientific) and stored at 4°C for microscopy.

Imaging and Measurements

Images were taken with AxioObserver.Z1 with Apotome using ZEN blue 2.3 software with Tiles and Position module (all from Carl Zeiss, Oberkochen, Germany). Images from at least 4 different brain slices of the medial dorso-lateral telencephalon were taken at 20× magnification. For all markers with exception of the apoptosis marker cleaved caspase 3 (CC3) images were taken with apotome and Z-stack mode with 1-µm steps. For CC3 standard fluorescence images from the whole hemisphere were taken. CC3-positive cells were counted with ZEN blue 2.3 in the cortex from the dorsal to ventral site. Mitotic cells (phH3-positive cells) were counted with ZEN blue 2.3 within different layers of a 500-µm-wide cortical columns. Neurons (NeuN-positive), apical progenitor (AP) cells (Pax6-positive), and intermediate progenitor (IP) cells (Tbr2-positive) were counted within 200-µm-wide cortical columns using ImageJ. Tbr2-positive, phH3-positive, and NeuN-positive cells were counted through all Z-stacks of the corresponding brain slices. Pax6-positive, Tbr1-positive, Ctip2-positive, and Satb2-positive cells were counted in the medial focal plane of each brain slice. The boundary between the ventricular zone (VZ) and subventricular zone (SVZ) was defined by the shape of the nucleus and the density of Pax6-positive and Tbr2-positive cells. While most cells in the VZ show a stretched shape of the nucleus, cells in the SVZ possess an elliptical nucleus. In addition, the VZ was defined by its high density of Pax6-positive cells and SVZ was defined by its high density of Tbr2-positive cells where the basal decreasing density of cells marks the SVZ-intermediate zone (IZ) boundary (23). For quantification of mitotic cells in the hippocampal area, all phH3-positive cells were counted and subsequently correlated to the analyzed area. For adequate presentation, mitotic cell numbers were calculated to cells per mm³. For vascularization analyses, the medial focal plane of each brain slice was used. Subsequently, binary images were created with a fixed threshold and the percentage of the covered area excluding the meninges was computed. The thicknesses of the cortex and the cortical plate (CP) of each fetus were measured from the ventricular surface or cortical subplate to the pial surface. For this purpose, at least 5 positions from dorsal to ventral along the ventricle (100-µm intervals) were analyzed in 3 sections of the medial cortex of each fetus.

Statistics

All statistics were performed with RGUI 3.4.1 (R Foundation for Statistical Computing, Vienna, Austria). If not otherwise stated, statistical significance was evaluated by unpaired two-sided *t*-test. The number of analyzed fetuses, gathered from at least 3 independent litters, is indicated by "n." The significance level was set to 0.05.

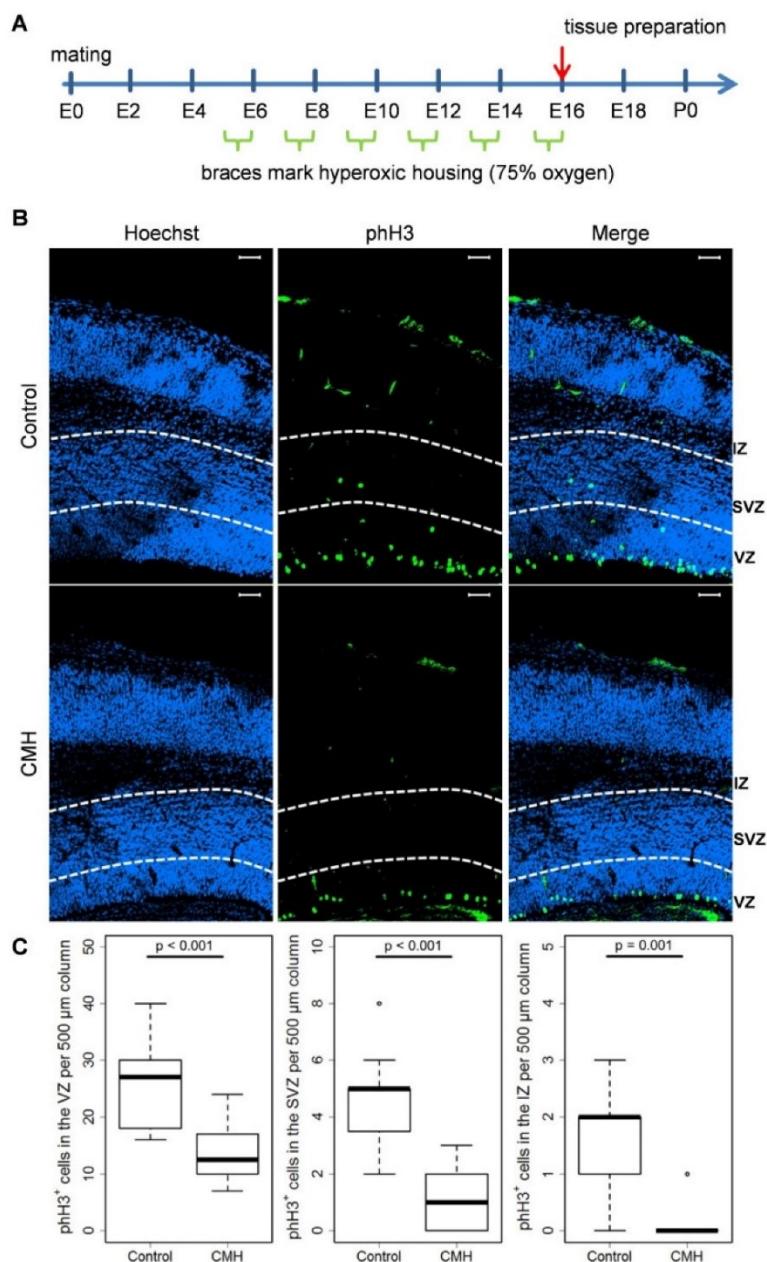

FIGURE 1. Chronic maternal hyperoxygenation (CMH) in mice leads to reduced mitosis in E16 dorso-lateral cortices. **(A)** Experimental setup. Timed-pregnant mice were treated from E5 to E16 with cycles of 75% oxygen for one day followed by one day at room air. Controls were kept at room air. **(B)** Representative immunofluorescence images of mitotic cells (phH3-positive cells, green) counterstained with Hoechst (blue). Dashed lines separate ventricular zone (VZ), bottom, subventricular zone [SVZ], mid, and intermediate zone [I_Z], top. Scale bars: 50 μ m. **(C)** Quantification of phH3-positive mitotic cells within VZ, SVZ, and I_Z in 500- μ m-wide columns. Bars represent significant differences with displayed p-values (unpaired two-sided t-test or Wilcoxon-test for phH3-positive in the I_Z; n = 9).

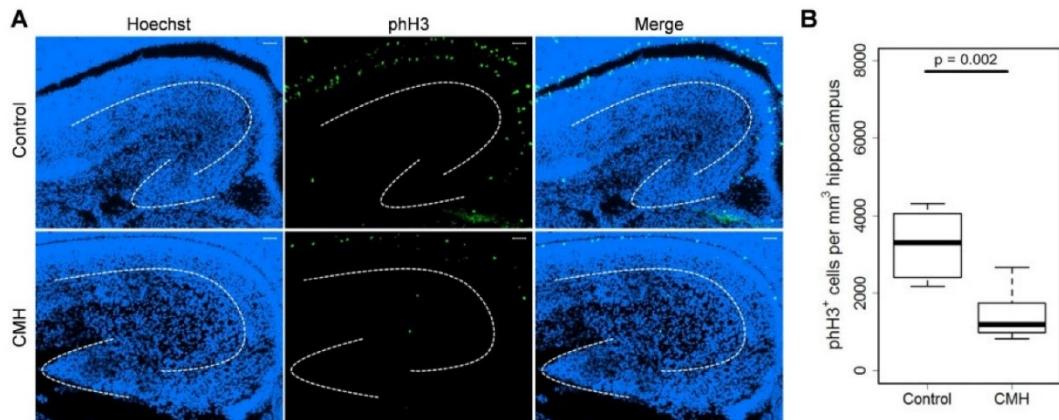

FIGURE 2. Chronic maternal hyperoxegenation (CMH) reduces early hippocampal mitosis in E16 mouse fetuses. **(A)** Representative immunofluorescence images of mitotic cells (pH3-positive cells, green) counterstained with Hoechst (blue). Dashed lines indicate CA1-CA3 region (top, right) and the hippocampal fissure (bottom, left). Scale bars: 50 µm. **(B)** Quantification of pH3-positive mitotic cells density in the early hippocampus. Bar represents significant difference with displayed p values (unpaired two-sided t-test; n = 6).

RESULTS

Maternal Hyperoxegenation Differentially Affects Proliferation in the Developing Brain Depending on Exposure Length

Short-term (48 hours) maternal hyperoxegenation leads to increased fetal brain oxygen tension and shows developmental stage-dependent effects in the proliferating zones of the mouse brain with enhancing progenitor cell proliferation, particularly in the IZ during late neurogenic phase of brain development (E14–E16), but expressed no effects in the earlier expansion/neurogenic phase from E10–E12 (12). The effects of CMH covering the expansion and neurogenic phase remained unclear. We therefore treated pregnant C57BL/6J mice from E5 to E16 with cycles of 75% oxygen for one day followed by one day at room air (Fig. 1A; intermittent treatment scheme was applied to avoid toxic effects on the adult mother [12]). The results were compared with control mice kept at room air ensuring the same environmental conditions besides the oxygen treatment. Representative immunofluorescence images of mitotic cells marked by pH3 in the VZ, the SVZ and the IZ representing the proliferating zones in the developing mouse brain from apical to basal membrane are displayed in Figure 1B. In contrast to short-term hyperoxegenation (12), quantitative immunohistochemistry analyses revealed that CMH-treated mice showed a significantly reduced number of mitotic cells by a factor of 0.5 in the VZ, 0.2 in the SVZ and nearly depleted in the IZ compared with controls (Fig. 1C). To investigate whether reduced cell proliferation is limited to the cortical area, we additionally analyzed cell proliferation within the developing hippocampal formation. These analyses revealed that CMH also affects hippocampal development with reduced mitotic activity in the VZ of the hippocampus (Fig. 2).

Early CMH Reduces the Number of AP but Not IP Cells

We next ascertained whether the differential effects on cell proliferation of short-term versus chronic maternal hyperoxia translates into different numbers of the various progenitor cell types of mouse developing cortex. The first population comprises dividing Pax6-positive radial glial cells as one major type of AP at the ventricular surface of the VZ (24–31). The second class of neural progenitors originate from radial glial cells by asymmetric mitoses are referred to as Tbr2-positive IPs and form the SVZ (29, 30, 32–35). CMH led to a morphological thinner VZ compared with normoxic controls. We found that there were reduced numbers of Pax6-positive cells compared control conditions with pronounced effects in the VZ (Pax6-positive cells reduced by a factor of 0.8), while the SVZ was not affected (Fig. 3).

To analyze IPs as the second major class of neural progenitors, we performed quantitative histology on Tbr2-positive cells. CMH did not change Tbr2-positive IP cell counts in any cell layer (Fig. 4). To clarify whether the specific reduction of Pax6-positive cells arises from reduced proliferation only or from apoptotic effects, we performed immunohistochemistry for the apoptosis marker CC3. Both CMH-treated and control mice showed few apoptotic cells but with no difference between both groups (Fig. 5A, B). Because Wagenführ et al and Lange et al showed vascularization effects associated with oxygenation (12, 20), we additionally performed immunohistochemical staining for IB4 as an established marker for vessels (Fig. 5C, D). Quantification of percentual vessel covered area revealed no differences between CMH-treated mice and control mice (Fig. 5D). In summary, CMH treatment of the fetal brain resulted in specific reduction of Pax6-positive AP production, but did not change the generation of IPs. This specific reduction of Pax6-positive

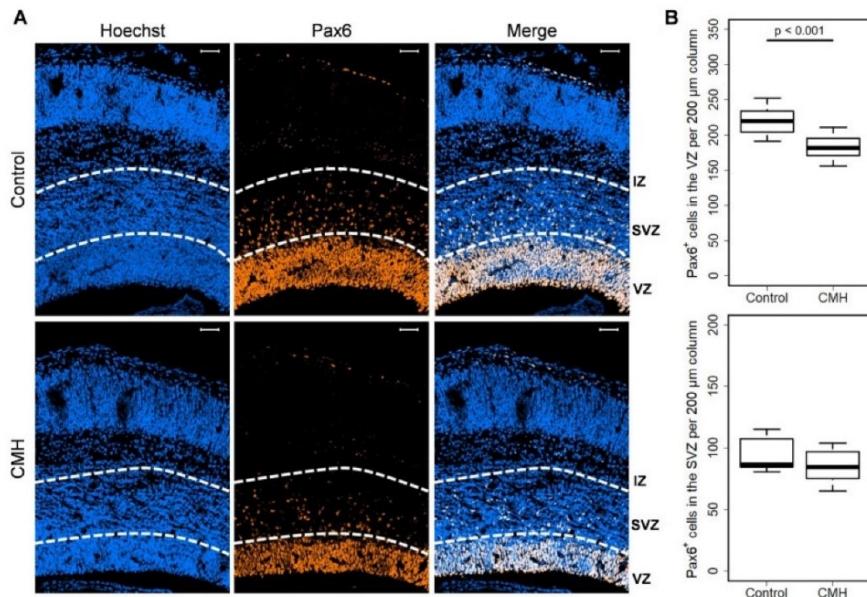

FIGURE 3. Chronic maternal hyperoxygenation (CMH) in mice reduces the number of basal progenitor cells in E16 dorso-lateral cortices. **(A)** Representative immunofluorescence images of basal progenitor cells (Pax6-positive cells, orange) counterstained with Hoechst (blue). Dashed lines separate ventricular zone ([VZ], bottom, subventricular zone [SVZ], mid, and intermediate zone [IZ], top). Scale bars: 50 μ m. **(B)** Quantification of Pax6-positive basal progenitor cells within VZ and SVZ in 200- μ m-wide columns; bars represent significant differences with displayed p values (unpaired two-sided t-test; n = 8 for controls, n = 10 for CMH).

APs likely arises from reduced proliferation, but not due to apoptosis or altered vascularization.

Early CMH Treatment Results in Altered Cortical Development

The proliferating zones near the apical surface constantly contribute neurons to the CP forming its typical inside-out layer pattern during cortical development (36). Pax6 represents a key factor in this highly orchestrated process (37). We next investigated whether the effects of CMH on progenitor cell proliferation and particularly the number of Pax6-positive APs translated into an alteration of the development of the CP. Immunofluorescence images of the rostral telencephalon revealed an aberrant NeuN expression profile in the CP in CMH-treated fetal brains. While NeuN expressing cells clearly mark the subplate and deeper layers of the CP, cells in the upper layers showed less NeuN expression (Fig. 6A). Quantification of NeuN expression using fixed illumination settings thereby resulted in a reduced number of NeuN-positive cells by a factor of 0.8 in the rostral CP (Fig. 6B). However, the aberrant NeuN expression profile in the upper layers of CP did not result in morphological changes since cortical thickness was not affected in CMH-treated mice compared with controls (Fig. 6C). This prompted us to analyze the individual cortical layers with a combination of Tbr1, Ctip2, and Satb2 markers. Immunohistochemical investigation of

these markers revealed a reduced number of Satb2-positive cells representing upper layer neurons in CMH-treated fetuses. Despite this, the numbers of deeper layer neurons stained with Tbr1 were increased while the number of Ctip2-positive cells were unaffected (Fig. 7). In summary, CMH-treated mice were grossly morphologically unaffected but showed an altered cortical layering. There were more deeper layer neurons originating in early development but fewer upper layer neurons originating in later development in CMH-treated fetuses.

DISCUSSION

Maternal hyperoxygenation is used to treat heart hypoplasia in fetuses (4–6). Although there are promising effects regarding heart hypoplasia, maternal hyperoxygenation also influences neuronal development by specifically affecting neurogenesis (12, 20). While these *in vivo* studies addressed only short-term hyperoxygenation, the present study investigates the effects of CMH as a novel clinical approach on cortical development compared with normoxic controls. We thereby demonstrated that CMH with 75% oxygen affected the cortical development of C57BL/6J mouse fetuses, but in an opposite way compared with short-term maternal hyperoxygenation: While short-term maternal hyperoxygenation for 48 hours enhances the number of mitotic cells in the SVZ at developmental stage E14–E16 but has no effects at E10–E12, CMH from E5 to E16 leads to a significant reduction of mi-

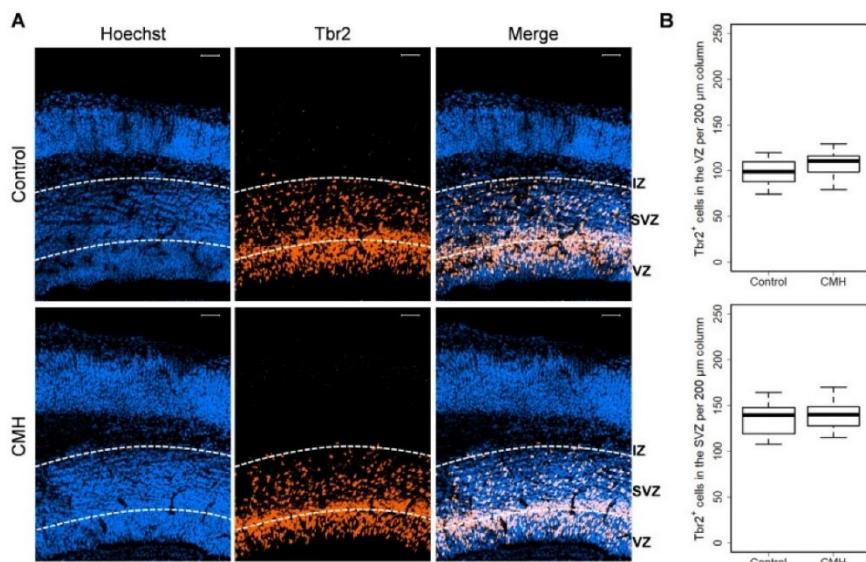

FIGURE 4. Intermediate progenitor cells in dorso-lateral cortices of E16 mice remain unaffected by chronic maternal hyperoxigenation (CMH). **(A)** Representative immunofluorescence images of intermediate progenitor cells (Tbr2-positive cells, orange) counterstained with Hoechst (blue). Dashed lines separate ventricular zone (VZ), bottom, subventricular zone (SVZ), mid, and intermediate zone (IZ), top. Scale bars: 50 µm. **(B)** Quantification of Tbr2-positive intermediate progenitor cells within VZ and SVZ in 200-µm-wide columns. Unpaired two-sided *t*-tests revealed no significant differences between control and CMH animals for all layers (n=8).

totic cells in all proliferating zones of the developing cortex. Because mitosis in the very early hippocampal development was also reduced, we conclude that this effect is likely not limited to the developing cortex.

To investigate the affected cell populations in the proliferating zones of the developing cortex, we next performed immunostainings for APs and IPs. Here, CMH leads to significantly reduced numbers of Pax6-positive cells representing APs going along with a morphologically thinner VZ. Unexpectedly, the number of sequentially resulting IPs was not affected (33). When comparing to short-term hyperoxigenation of fetal brain tissue, we suppose that there is a critical length and/or developmental stage for the effects of hyperoxigenation on neuroprogenitor populations. While short-term hyperoxigenation for 48 hours from E10 to E12 does not lead to significant changes in the number of IPs (12), a 72-hour period from E10 to E13 shifts the progenitor population from APs to an increased number of IPs as also was observed in the later midneurogenic phase at E14–E16 (12, 20). Since our CMH treatment scheme covers the developmental stages from E5 to E16, we conclude that the longer oxygen application leads to the stronger shift toward neuroprogenitor differentiation. Excluding apoptotic effects, the unaffected number of IPs in CMH-treated mice might result from reduced mitosis during development—even in earlier developmental stages as investigated in short-term hyperoxigenation studies—which offsets the oxygen-driven differentiation of APs sequentially dividing in IPs (38). However, as we needed to include rescue days

with exposure of the dams to normal oxygen conditions (12), we cannot fully rule out that the sequential exposure or the exposure during very specific developmental processes might be—at least in part—also responsible for the contrary effects of CMH compared with short-term hyperoxigenation.

Since IPs contribute to cells of the CP via symmetric division and Tbr2 and Pax6 are both main regulators of cortical development, we investigated if CMH affect cortical morphology and NeuN expression as a marker for mature neurons (37, 39, 40). CMH induces an aberrant NeuN expression profile with reduced expression of NeuN in the upper cortical layers of rostral cortices. This aberrant NeuN expression profile could be the result of the decreased proliferation and subsequently reduced number of Pax6-positive APs, which may affect cortical neurogenesis. This hypothesis is supported by current evidence from Pax6 research, where timed and conditional knockout models show similar but more severe morphological changes compared with hyperoxic brains with markedly reduced numbers of neurons especially in superficial layers of the rostral cortex leading to severe decrease of brain sizes and hampered cognitive functions (37, 41). The more severe phenotype in Pax6 knockout models eventually leading to smaller brain sizes, which were not observed in CMH-treated mice, might be explained by the more consequent knock-out of Pax6-positive APs in genetic models compared with CMH animals. To deepen our knowledge of the underlying mechanisms, we have used Tbr1, Ctip2, and Satb2 antibodies as a panel of cortical layer markers. In CMH-treated

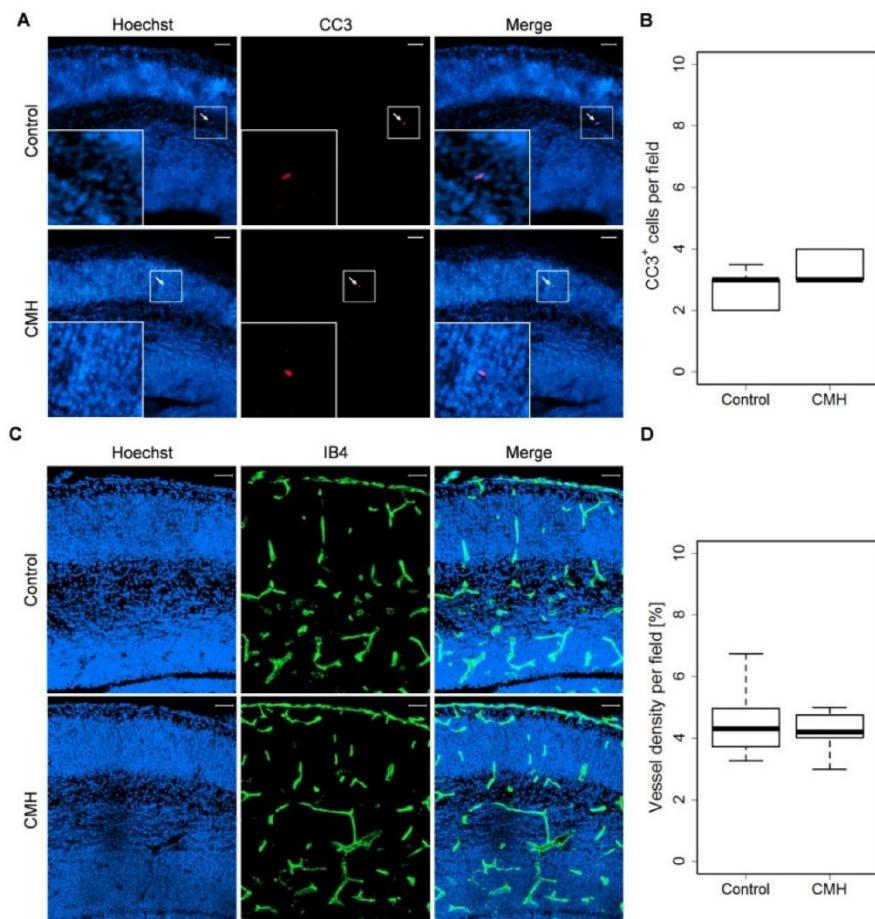

FIGURE 5. Apoptosis rate and vascularization in the E16 mouse cortex are not affected by chronic maternal hyperoxygenation (CMH). **(A)** Representative immunofluorescence images of apoptotic cells (cleaved caspase 3 [CC3]-positive cells, red) counterstained with Hoechst (blue). White arrows indicate apoptotic cells. White square is shown magnified in the left corner. Scale bars: 50 µm. **(B)** Quantification of CC3-positive apoptotic cells counted in the medial cortex per brain slice. Wilcoxon rank sum test revealed no significant differences between control and CMH animals ($n = 6$). **(C)** Representative orthogonal projected immunofluorescence images of vessels (IB4-positive, green) counterstained with Hoechst (blue). Scale bars: 50 µm. **(D)** Quantification of vessel density (IB4-positive) in the early hippocampal area. Unpaired two-sided *t*-test revealed no significant differences between control and CMH animals ($n = 6$).

mice, the reduced number of Satb2-positive cells that represent upper layer neurons supports our results of the aberrant NeuN expression profile. Interestingly, the number of deeper layer neurons represented by Tbr1-positive cells is enhanced. Since our CMH treatment protocol covers the early neurogenic expansion phase, an early increased proliferation leading to an exhaustion of proliferation capacity at E16 could be possible. Thereby, a probable increased proliferation at earlier stages could lead to relatively unremarkable cortical morphology, but reduced proliferation in later stages (42, 43). In addition, this theory would explain the increased number of deeper

layer neurons that arise at earlier stages. Consequently, with exhaustion of proliferative capacities, which may lead also to the demonstrated reduced number of Pax6-positive cells at E16, the number of upper layer neurons is decreased. However, we cannot exclude other hypothesis that could be an aberrant migration and/or maturation, where the specific events of cortical development are delayed in CMH-treated mice or hampered migration occurs (44–46). Therefore, further studies are needed to investigate the specific effects of CMH protocols on the developing brain at various of developmental stages.

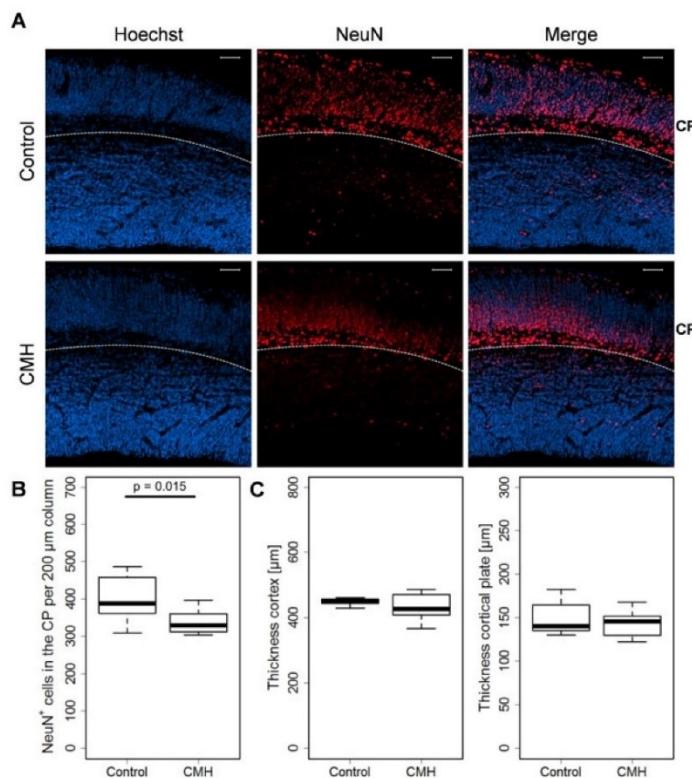

FIGURE 6. Chronic maternal hyperoxygenation (CMH) disturbs proper cortical layering in E16 mouse brain. **(A)** Representative immunofluorescence images of NeuN expressing neurons (red) counterstained with Hoechst (blue). Dashed lines separate cortical plate (top) from basal cortical zones (bottom). Scale bars: 50 μm . **(B)** Quantification of cortical NeuN-positive neurons within the cortical plate in 200- μm -wide columns. **(C)** Quantification of radial thickness of the cortex and the cortical plate. Bars represent significant differences with displayed p-values (unpaired two-sided t-test; n = 9 for NeuN-positive quantification; n = 7 for radial thickness measurements). CP, cortical plate.

A recent clinical pilot study investigating the effects of CMH for treatment of heart hypoplasia in humans resulted in a reduction of head growth in 6-month-old infants who underwent CMH therapy *in utero* (22). Therefore, Edwards et al adjusted their treatment protocol using longer daily exposure but with a lower fraction of inspired oxygen (FiO_2) and added evaluations of placental health, fetal head growth, and cerebral maturity. Although, the infants showed no differences in neurodevelopmental testing compared with controls, the study by Edwards et al together with our data indicate that intense or very early CMH treatment schemes may lead to abnormal neural development with contrary results to short-term hyperoxygenation. A direct comparison with our data is limited by oxygenation exposure, treatment protocol and species. Edwards et al started their treatment protocol around gestational week 26 with ~50% fraction of inspired oxygen controlled by analysis of the maternal arterial partial pressure of oxygen. We here used 75% oxygen, known to be effective in mice and for the comparability with short-term hyperoxygenation protocols, but we were technically not able to measure blood oxy-

genation due to handling issues within the oxygen chamber and to avoid any form of stress (12, 21). Additionally, we used a CMH protocol that starts at E5 to include the neural stem cell expansion phase and therefore we cannot exclude specific effects raised in the early treatment phase. Particularly, the increased number Tbr1-positive cells indicate early effects of the oxygen treatment. Nevertheless, both specialized treatment schemes raise concerns about the effects of CMH on proper development of the brain.

In conclusion, maternal hyperoxygenation leads to increased oxygen tension in fetal brain tissue and affects cortical development in mice with a specific pattern depending on timing and length within the developmental process. While short-term maternal hyperoxygenation during midneurogenic phase can even enhance neurogenesis, a longer and very early oxygen application, such as CMH leads to severe reduction of proliferation and numbers of APs, likely ending in reduced neuron numbers and brain size as well as hampered cognitive functions (41). Although the consequences of maternal hyperoxygenation on brain function, such as cognition need to be determined, the

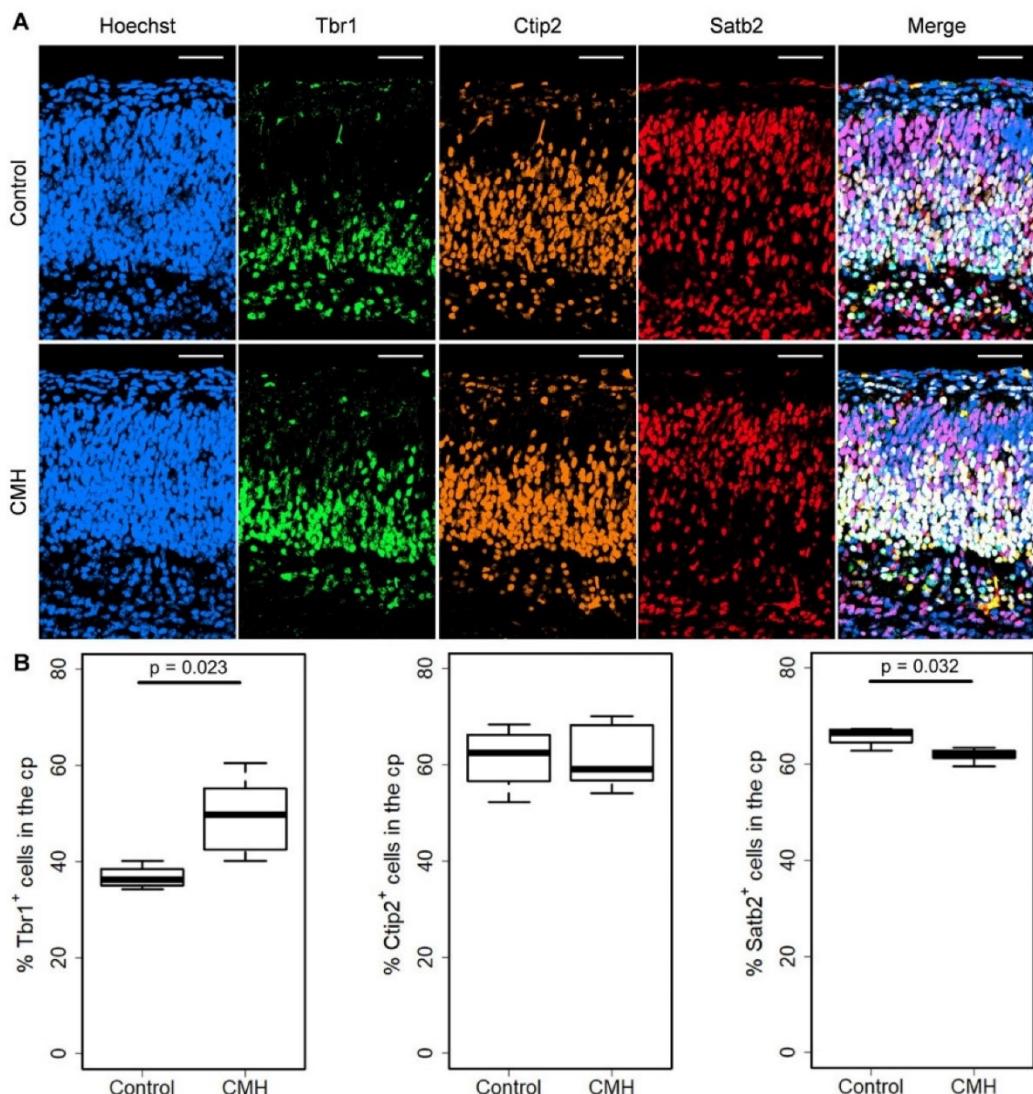

FIGURE 7. Chronic maternal hyperoxygenation (CMH) changes the distribution of neurons within the cortical layers. **(A)** Representative immunofluorescence images of Tbr1 (green), Ctip2 (orange), and Satb2 (red) expressing neurons counterstained with Hoechst (blue). Scale bars: 50 µm. **(B)** Quantification of cortical Tbr1-positive, Ctip-positive, and Satb2-positive neurons as percentage of all cells within the cortical plate (CP). Bars represent significant differences with displayed p values (unpaired two-sided t-test; n = 4 for controls; n = 5 for CMH).

effects of long-time maternal hyperoxygenation protocols on brain development require clarification. Further studies are thus needed to investigate the pathophysiological mechanisms underlying these findings and to assess the clinical and neurodevelopmental outcomes of the pups.

ACKNOWLEDGMENTS

We thank the team of the core facility Zentrale Versuchstierhaltung at the University of Rostock for providing the timed-pregnant mice and Uta Naumann, Jette Abel, and Franziska Alfen for their technical assistance.

4.3 Catecholaminergic Innervation of Periventricular Neurogenic Regions of the Developing Mouse Brain

Mareike Fauser, Grit Weselek, Christine Hauptmann, Franz Markert, Manfred Gerlach, Andreas Hermann & Alexander Storch

Frontiers in Neuroanatomy, 2020, Band 14, Artikel 558435

Zusammenfassung:

In dieser Studie wurde der Einfluss der Katecholamine Dopamin (DA) und Noradrenalin (NA) auf die fetale Neurogenese in verschiedenen Regionen des Gehirns untersucht. Dazu wurden die ventrikulären bzw. subventrikulären Zonen, welche das gesamte Ventrikelsystem umgeben, von verschiedenen Hirnregionen zu den Embryonalstadien (E) 14,5, E16,5 und zum Postnatalstadium (P) 0 isoliert und mittels HPLC auf ihren DA- und NA-Gehalt sowie mittels Immunhistochemie auf die Anzahl an MCM2⁺ neuralen Stammzellen hin untersucht. Die Ergebnisse zeigen von E14,5 zu P0,5 eine kontinuierliche Abnahme an Stammzellen in allen Regionen. Der NA-Gehalt der jeweiligen Zonen steigt in diesem Zeitraum kontinuierlich an, während der DA-Gehalt nur an den lateralen Ventrikel zunimmt, in allen anderen Regionen allerdings abnimmt. Dabei offenbart sich eine starke inverse Korrelation der Anzahl an Vorläuferzellen mit dem NA-Gehalt der jeweiligen Regionen, nicht jedoch mit dem DA-Gehalt. Dies deutet auf einen potenziellen inhibitorischen Effekt durch NA auf die Vorläuferzellen des periventrikulären Systems während der Gehirnentwicklung hin. Die Daten stellen die Grundlage für weitere funktionelle Untersuchungen von Katecholaminen und insbesondere der noradrenergen Innervation und deren potenziell inhibitorischen Effekt auf neurale Stammzellen während der Entwicklung des Gehirns dar.

Catecholaminergic Innervation of Periventricular Neurogenic Regions of the Developing Mouse Brain

The major catecholamines—dopamine (DA) and norepinephrine (NE)—are not only involved in synaptic communication but also act as important trophic factors and might ultimately be involved in mammalian brain development. The catecholaminergic innervation of neurogenic regions of the developing brain and its putative relationship to neurogenesis is thus of pivotal interest. We here determined DA and NE innervation around the ventricular/subventricular zone (VZ/SVZ) bordering the whole ventricular system of the developing mouse brain from embryonic day 14.5 (E14.5), E16.5, and E19.5 until postnatal day zero (P0) by histological evaluation and HPLC with electrochemical detection. We correlated these data with the proliferation capacity of the respective regions by quantification of MCM2⁺ cells. During development, VZ/SVZ catecholamine levels dramatically increased between E16.5 and P0 with DA levels increasing in forebrain VZ/SVZ bordering the lateral ventricles and NE levels raising in midbrain/hindbrain VZ/SVZ bordering the third ventricle, the aqueduct, and the fourth ventricle. Conversely, proliferating MCM2⁺ cell counts dropped between E16.5 and E19.5 with a special focus on all VZ/SVZs outside the lateral ventricles. We detected an inverse strong negative correlation of the proliferation capacity in the periventricular neurogenic regions (log-transformed MCM2⁺ cell counts) with their NE levels ($r = -0.932$; $p < 0.001$), but not their DA levels ($r = 0.440$; $p = 0.051$) suggesting putative inhibitory effects of NE on cell proliferation within the periventricular regions during mouse brain development. Our data provide the first framework for further demandable studies on the functional importance of catecholamines, particularly NE, in regulating neural stem/progenitor cell proliferation and differentiation during mammalian brain development.

Keywords: brain development, ventricular zone, catecholamines, norepinephrine, dopamine, neurogenesis

INTRODUCTION

There is a multitude of research exploring the distribution of the major catecholamines—namely dopamine (DA) and norepinephrine (NE, also called noradrenaline)—in the mammalian brain including mammalian brain development. Noradrenergic neurons in the Locus coeruleus (LC) as the major noradrenergic formation in the mammalian brain are among the earliest born neurons followed by the dopaminergic system in later embryonic stages (Coyle, 1977; Steindler and Trosko, 1989; Pattyn et al., 2000; Aroca et al., 2006). LC neurons widely spread all over the brain with the striatum as one major exception (Foote et al., 1983; Erdtsieck-Ernste et al., 1991; Aston-Jones et al., 1995). Although the LC noradrenergic neurons are born early in development at around murine embryonic day 9 (E9)–E11 (all embryonic stages in this article are adapted to mouse embryonic ages post-fertilization through Carnegie stage comparisons; Lauder and Bloom, 1974; Coyle, 1977; Coyle and Molliver, 1977), the ascending noradrenergic projections throughout the brain needs several more days and reach the diencephalon at E13–E14 and cortical regions at E16–E17 with an increase in NE content as measured by HPLC of various brain areas starting around E15 to E17 in rodents depending on the brain region (Olson and Seiger, 1972; Lauder and Bloom, 1974; Coyle, 1977; Kohno et al., 1982; Berger and Verney, 1984; Murrin et al., 2007). The cortical distribution and density of NE fibers achieve their final pattern at postnatal day 7 (P7) and the adult extent in the 3rd to 4th postnatal week (Berger and Verney, 1984; Murrin et al., 2007). Similarly, tyrosine hydroxylase (TH) immunoreactivity in the ventral midbrain is detected from E11 to E12, and DA immunoreactivity is found from E12 (Olson and Seiger, 1972; Lauder and Bloom, 1974; Tomasini et al., 1997). This again contrasts with the later increase in DA tissue content from E13 to E15 (Ribary et al., 1986; Tomasini et al., 1997). The reported time offset between cellular and histological development of catecholaminergic systems and their subsequent functional development urgently necessitates the additive measurement of tissue levels of catecholaminergic neurotransmitters. Together, the development of both major catecholaminergic systems of the mammalian brain starts at a similar embryonic (postconceptional) age, is well pronounced during late embryonic development, and become functional just before birth. However, the available studies on catecholaminergic systems development strongly focused on neurotransmitter function within the nigrostriatal and mesolimbic dopaminergic system and the LC noradrenergic system innervating the cerebral cortex.

Catecholamines are not only involved in synaptic communication but also act as important trophic factors (Felten et al., 1982; Gustafson and Moore, 1987; Berger-Sweeney and Hohmann, 1997). In this respect, NE is considered to play a trophic role in brain maturation particularly cortical dendritic structuring (Felten et al., 1982; Gustafson and Moore, 1987; Berger-Sweeney and Hohmann, 1997). However, most studies used mechanical or toxic lesions of the NE system

during the early postnatal period and only addressed cortical development (for review see Berger-Sweeney and Hohmann, 1997). The one study using prenatal lesioning of the NE system by intrauterine 6-hydroxydopamine application at E17 revealed no major alterations in cortical morphology in adulthood but did not study other brain regions (Lidov and Molliver, 1982). The more recent approach to disrupt NE innervation by knocking-out the gene encoding for dopamine- β -hydroxylase (DbH), the rate-limiting enzyme of NE production, showed that NE is essential for rodent fetal development with almost 100% mortality within the first days of life (Thomas et al., 1995). The brain morphology of these animals has however not been reported in detail yet. Substitution of NE by L-3, 4-dihydroxyphenylserine (DOPS) bypassing DbH restored NE synthesis and completely rescued the survival of DbH knock-out animals. However, in these mice, the postnatal development of the cerebellum and the noradrenergic systems was independent of NE (Jin et al., 2004). The reason for the prenatal mortality of DbH knock-out mice remains unclear but is most likely due to cardiovascular instability, which for unknown reasons stabilizes shortly after birth allowing the withdrawal of DOPS supplementation. Whether this instability arises from central or peripheral pathology remains enigmatic. The lethal phenotype without indirect NE supplementation during crucial developmental stages makes it impossible to accurately study embryonic/fetal brain development under NE depletion in this model. These data together with the recently described role of norepinephrine as a negative regulator of neural stem cell proliferation in the adult brain (Weselek et al., 2020) raised the question of whether catecholamines show analogous trophic actions during embryonic brain development beyond cortical development. We therefore comparatively determined the catecholaminergic innervation and the neural stem/progenitor cell proliferation capacity of the ventricular zone/subventricular zone (VZ/SVZ) bordering the whole ventricular system of the developing mouse brain from E14.5 until postnatal day zero (P0).

MATERIALS AND METHODS

Animals and Tissue Processing

Whole brains were dissected from embryos from timed-pregnant C57BL/6J mice at E14.5, E16.5, E19.5 (histology only), or newborn C57BL/6J mice (P0). All animal protocols were reviewed and approved by Animal Welfare Committee at the Technische Universität Dresden and Landesdirektion Sachsen, Dresden, Germany (governmental authorities). The tissue was fixed for 24 h in 4% paraformaldehyde (Merck, Darmstadt, Germany) and kept in 30% sucrose (Carl Roth, Karlsruhe, Germany) in PBS (Thermo Fisher Scientific, Waltham, MA, USA). Then brains were snap-frozen, coronal sections at 20 μ m thickness were prepared using a cryotome (Leica Biosystems, Nussloch, Germany) and mounted on Superfrost Plus slides (Thermo Fisher Scientific, Waltham, MA, USA). The slides were stored at 4°C until staining. A total of three animals per group were examined for each experiment; all data

were gathered from randomly chosen fetuses from three independent litters.

Immunohistochemistry

Cryosections were pre-incubated in 3% blocking donkey serum (Jackson Immunoresearch, West Grove, IA, USA) containing 0.2% Triton X-100 (Thermo Fisher Scientific, Waltham, MA, USA) in PBS for 2 h at room temperature and then incubated overnight at 4°C with primary antibodies followed by secondary fluorescence conjugated antibodies for 1 h at room temperature. Cell nuclei were counterstained with 4,6-diamidino-2-phenylindole (DAPI, Thermo Fisher Scientific, Waltham, MA, USA). The following primary antibodies were used: sheep or rabbit anti-TH 1:500 (Pel-Freez, Rogers, Arkansas, RRID:AB_461070 and RRID:AB_461064); mouse anti-Nestin 1:500 (Chemicon, Thermo Fisher Scientific, RRID:AB_2251134); rat anti-DAT 1:500 (Merck, RRID:AB_2190413); rabbit anti-MCM2 1:500 (Abcam, Cambridge, UK, RRID:AB_881276; mouse anti-NET 1:200 (MAB Technologies, Neenah, WI, USA, RRID:AB_2571639). Fluorescence labeled secondary antibodies were purchased from (Molecular Probes, Thermo Fisher Scientific, Waltham, MA, USA). Images were captured using a fluorescence microscope (Leica DM IRE2, Wetzlar, Germany) or a Zeiss confocal microscope (LSM 700; Zeiss, Oberkochen, Germany) equipped with DAPI/UV, krypton, krypton/argon, and helium lasers.

HPLC Assay of Tissue Catecholamine Content

Tissue from the same periventricular regions (200 µm surrounding the ventricles) as those used for immunohistochemistry was microdissected from mouse brains at E14.5, E16.5, P0 and adult (8–12 weeks of age, male). For this purpose, the brains were removed from out of the skull and sliced into coronal sections of approximately 1 mm which were kept on ice or a cooling plate until further preparation. With the help of a dissection microscope (magnification: ×100) approximately 200 µm tissue surrounding the ventricles at the appropriate zone was removed by one experienced experimenter (Grit Weselek) and the pieces were snap-frozen in liquid nitrogen. The 200 µm were chosen to secure enough material for HPLC analysis while including the major part of VZ/SVZ. For further HPLC analysis, the tissue samples were thawed, weighed, and sonicated in 0.05 M perchloric acid for 60 s resulting in 10% (w/v) homogenate suspensions. The mean ± s.e.m. weights of tissue samples of 22 ± 2 (range: 9–45) mg per tissue sample were in the typical range of previous studies (Wagner et al., 1982) and did not show any significant differences between experimental conditions (two-way ANOVA with VZ regions and developmental stages as fixed factors revealed no significant interaction effect of VZ regions and stages on tissue sample weights ($p = 0.225$, F -value = 1.4) and no significant differences among VZ regions ($p = 0.468$, F -value = 0.9) and stages ($p = 0.840$, F -value = 0.2). These were centrifuged at 48,000× g for 20 min at 4°C, and 50 µl samples of the supernatants injected directly into high-performance liquid chromatography (HPLC) system with electrochemical detection (Gynkotek

GmbH, Germering, Germany) for analysis of tissue DA, NE, and epinephrine according to the method described in detail previously (Wagner et al., 1982; Gerlach et al., 1996; Kuhn et al., 1996). The HPLC system consisted of an AGILENT 1100 series (Bio-Rad, Munich, Germany), a Nucleosil 120-5C18 reverse phase (250 × 4.6 mm) analytical column (Macherey-Nagel, Düren, Germany), an electrochemical detector (model 1640; Bio-Rad, Munich, Germany). Detector data were recorded and analyses using an AGILENT Chem Station for LC9D (Bio-Rad). Concentrations were calculated from the peak height with the aid of an external standard. The detection limit of the HPLC system was 0.1 ng/ml (corresponding to 1 ng/g brain tissue) for all catecholamines. The investigator was blind to the experimental condition.

Cell Counting and Statistical Analysis

For quantification of proliferating mini-chromosome maintenance protein 2 (MCM2)⁺ cells within the ventricular zone/subventricular zone (VZ/SVZ) of the various periventricular regions [lateral wall of the lateral ventricles (LV_{lateral}), medial wall of the lateral ventricles (LV_{medial}), third ventricle (3V), aqueduct (Aq) and fourth ventricle (4V) according to the Prenatal Mouse Brain Atlas by Schambra (Schambra, 2008)], in any given experiment the number of MCM2⁺ cells was determined in a 130 µm section along the VZ/SVZ of every 12th coronal section using laser scanning confocal microscopy images processed with ImageJ [National Institutes of Health (NIH), Bethesda, MD, USA]. Data are displayed as normalized to 100 µm² VZ/SVZ surface area for each region. Statistical analyses were done with SPSS software, version 21.0 or newer (SPSS, Chicago, IL, USA). We applied various linear and nonlinear regression analyses and logarithm functions nicely matching the MCM2⁺ cell counts and NE levels and rendered a correlation coefficient (r^2) that was 0.858. Curve linearization was thus made by log transformation of results. Correlation analyses to assess the association of stem cell proliferation within the VZ/SVZ with catecholamine levels by using multiple linear regression analyses and Pearson correlation. Comparisons were made, as appropriate, with a two-sample t -test, Mann–Whitney U test, or χ^2 test. Two-sided p -values of less than 0.05 were deemed statistically significant.

RESULTS

Formation of a Rostrocaudal Proliferation Gradient Within the VZ/SVZ During Mouse Brain Development

Even though the proliferation capacity of the forebrain proliferative zone (ventricular zone/subventricular zone [VZ/SVZ]) bordering the lateral ventricles on their lateral side (LV_{lateral}) during mouse brain development is already described in detail, the time course of proliferation changes within the VZ/SVZ of the medial wall of the LV (LV_{medial}) and within the more caudal VZ/SVZ bordering the third ventricle (3V), the aqueduct (Aq) and the fourth ventricle (4V) is

not described in detail yet. To determine the proliferation capacity within the VZ/SVZ of the developing mouse brain, we here used the DNA replication licensing factor MCM2 as an established proliferation marker of Nestin⁺ neural stem/progenitor cells (von Bohlen und Halbach, 2011). As shown in Figures 1A,B, quantitative immunohistochemistry revealed a dramatic reduction to almost complete loss of proliferating (MCM2⁺) neural stem/progenitor cells within all proliferative zones between E14.5 and E19.5 except for the VZ/SVZ of LV_{lateral}. There were no relevant changes in proliferation patterns between E19.5 and P0. Together, we demonstrated the formation of a rostrocaudal gradient of the VZ/SVZ proliferation capacity during mouse brain development established between E14.5 and E16.5 and persisting until birth with high proliferation capacity in the rostral part (proliferative zone of the LV_{lateral}) down to a low proliferation capacity in the VZ/SVZ surrounding the third-to-fourth ventricle.

Catecholaminergic Innervation of the VZ/SVZ During Mouse Brain Development

Catecholaminergic innervation of the developing mouse brain was determined by immunostaining against the common catecholaminergic marker tyrosine hydroxylase (TH), the dopamine transporter (DAT), and norepinephrine transporter (NET) at E14.5, E16.5, and P0. Figure 2 shows representative immunohistological microphotographs of TH as well as of DAT and NET staining during mouse brain development. Histology data demonstrated an increase of TH⁺ fibers in all VZ/SVZ and adjacent regions during development after E14.5, but differential patterns of DAT⁺ and NET⁺ fibers: While DAT⁺ innervation increased between E16.5 and P0 within the striatum and the adjacent proliferative zone of the LV_{lateral}, we did not detect relevant changes in striatal NET⁺ fibers in the respective region. In all other VZ/SVZ regions, we detected no relevant changes in DAT⁺ fiber density during brain development (Figure 2). In contrast, NET⁺ fiber intensity displayed an increase during development after E14.5 in brain tissue surrounding the caudal VZ/SVZ regions of the 3V and Aq.

To confirm the functional catecholaminergic innervation of the VZ/SVZ, i.e., the actual catecholamine releases, we measured the levels of DA, NE, and epinephrine in microdissected proliferative zones periventricular regions containing the VZ/SVZ of the developing mouse brain at E14.5, E16.5, and P0 using an HPLC-electrochemical detection-based method. Since the thickness of the VZ/SVZ areas varies within the developing brain and changes during the developmental process and may thus not exactly correspond to the analyzed tissue samples, the preparation method used does not fully rule out partial contamination of HPLC samples with periventricular regions outside the VZ/SVZ. Nevertheless, in agreement with the DAT histology data, DA showed increased levels in the VZ/SVZ of the LV_{lateral} at P0, while there was a continuous decline during development in the caudal VZ/SVZ regions (Figure 3A, for statistics, refer to Supplementary Table S2). In contrast, in correspondence with the NET staining, NE levels showed continuously increasing levels in the caudal (hindbrain) VZ/SVZ

regions during development between E16.5 and P0 (Figure 3B, Supplementary Table S3). The pattern of catecholaminergic innervation was similar at P0 compared to the adult, even though the catecholamine levels in the adult brain were much higher compared to the developing brain (Supplementary Figure S1). We did not detect epinephrine/adrenaline (<1 ng/g brain tissue) in any VZ/SVZ region of the developing and adult mouse brain.

Correlations Between Catecholaminergic Innervation and Stem Cell Proliferation

We assessed potential associations of the periventricular proliferative capacity of MCM2⁺ neural stem/progenitor cells within the VZ/SVZ with periventricular DA and NE levels, developmental stages, and periventricular brain regions (Figure 4). Pearson correlation tests revealed correlations with a magnitude greater than |0.5| of log-transformed MCM2⁺ cell counts with NE levels (Pearson correlation coefficient $r = -0.932$; $p < 0.001$) and developmental stages ($r = -0.789$; $p < 0.001$). We found no correlations with a magnitude greater than |0.5| of log-transformed MCM2⁺ cell counts with DA levels ($r = 0.440$; $p = 0.051$) and brain regions ($r = -0.328$; $p = 0.117$). Multiple linear regression model analysis revealed that log-transformed MCM2⁺ cell counts were significantly associated only with NE levels (corrected $r^2 = 0.858$, $\beta = -0.701$, $p = 0.003$), but not with DA levels ($\beta = 0.045$, $p = 0.694$), developmental stage ($\beta = -0.264$, $p = 0.137$) or brain region ($\beta = -0.053$, $p = 0.674$). Hierarchical stepwise multiple regression analysis using sequences of F-tests confirmed that VZ/SVZ log-transformed MCM2⁺ cell counts were significantly correlated with NE levels.

DISCUSSION

We investigated the specific catecholaminergic innervation of the proliferative zones (VZ/SVZ) in the developing mouse brain and its putative association with their respective proliferation capacities throughout the ventricular system. We thereby demonstrate an inverse logarithmic correlation of the proliferation capacity of the VZ/SVZ with the NE content of the corresponding area during brain development, but no correlation with their DA levels. Since the NE neurotransmitter system develops after E14.5 in the midbrain/hindbrain regions bordering the ventricular system and omits the striatum, it is of particular relevance for the caudal VZ/SVZ regions. Figure 5 displays a graphical synopsis summarizing the association of the catecholaminergic neurotransmitter systems development with the proliferation capacity in the VZ/SVZ bordering the ventricular system from its rostral (forebrain LV_{lateral}) to the caudal parts within the midbrain/hindbrain (3V through 4V) during mouse brain development. These data imply that NE might be a putative humoral factor involved in the physiological decrease of neural stem/progenitor cell proliferation during prenatal development. Consistently, we recently detected a similar role of NE in the adult brain with inhibitory effects on the proliferative activity of adult

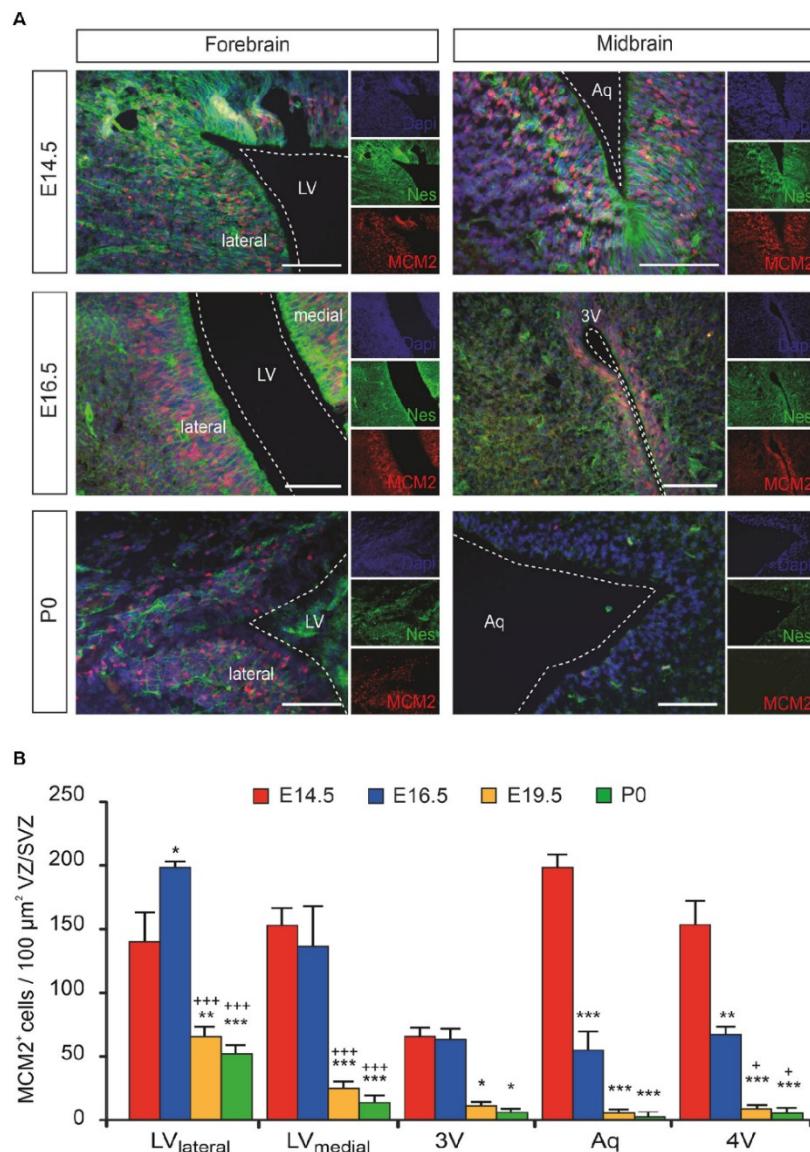

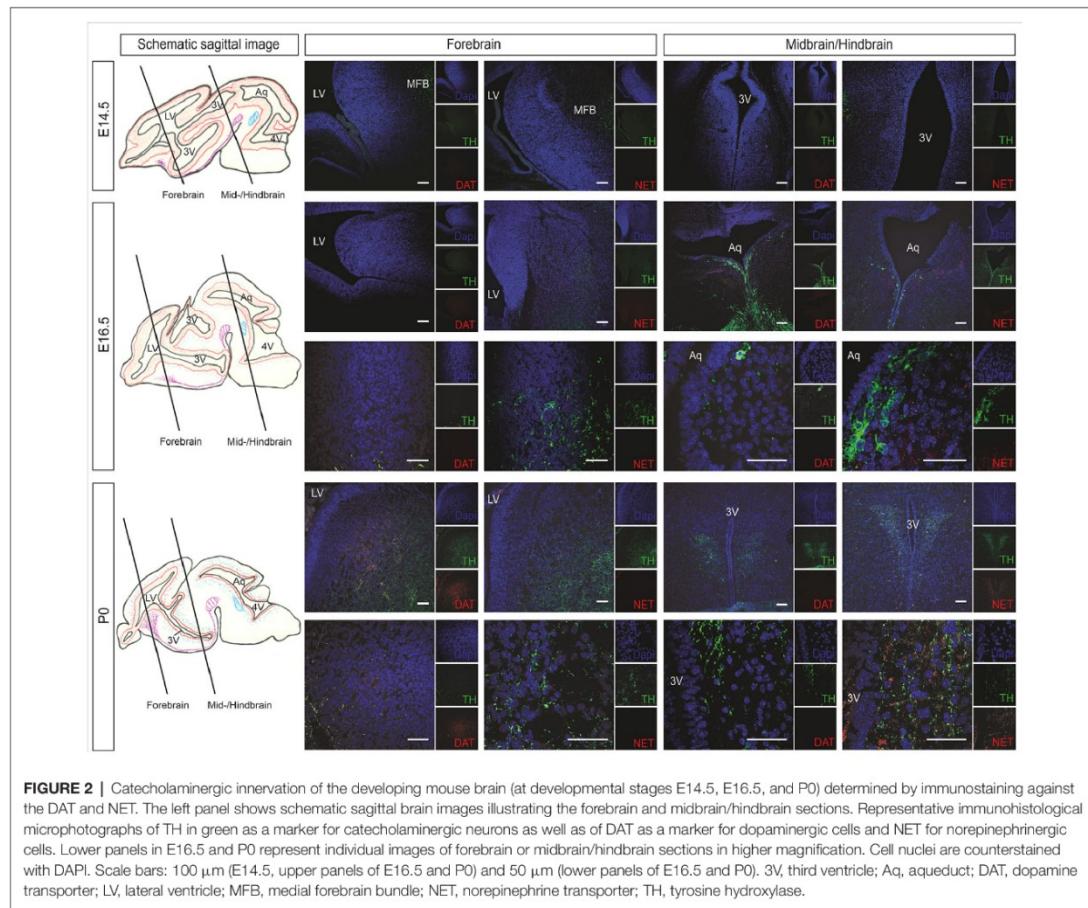

FIGURE 1 | The proliferation of ventricular/subventricular zone (VZ/SVZ) neural stem/progenitor cells (NPCs) within the developing mouse forebrain and midbrain at E14.5, E16.5, E19.5 (quantitative results only), and P0. **(A)** Proliferating stem/progenitor cells were co-stained with MCM2 (red) and Nestin (green) in VZ/SVZ. Cell nuclei are counterstained with 4,6-diamidino-2-phenylindole (DAPI). Scale bar: 50 μ m. **(B)** Quantitative immunohistochemistry revealed a dramatic reduction to almost complete loss of proliferating (MCM2*) cells during development within the VZ/SVZs except for the lateral VZ/SVZ of the lateral ventricles. Two-way ANOVA with *post hoc* t-test and Bonferroni adjustment with VZ/SVZ regions and developmental stages as fixed factors revealed that brain regions and embryonic stages had a significant interaction effect on MCM2* cells per 100 μ m² ($P < 0.001$, F -value = 5.7) and significant differences among VZ/SVZ regions ($P < 0.001$, F -value = 17.1) and embryonic stages ($P < 0.001$, F -value = 95.0). P -values from *post hoc* tests with Bonferroni adjustment are * $P < 0.05$, ** $P < 0.01$ and *** $P < 0.001$ when compared to E14.5 and * $P < 0.05$ and *** $P < 0.001$ when compared to E16.5 (only P -values among developmental stages are displayed for clarity; complete statistics in **Supplementary Tables S1A,B**). 3V, third ventricle; Aq, aqueduct; LV, lateral ventricle; LV_{lateral}, lateral wall of the lateral ventricles; LV_{medial}, medial wall of the lateral ventricles; MCM2, mini-chromosome maintenance protein 2; Nes, Nestin.

Ergebnisse

neural stem cells in the consecutive neurogenic regions (Weselek et al., 2020). However, the physiological significance of our present findings needs to be determined by functional studies, for example by pharmacologic or genetic manipulation of DA and/or NE levels during the various development stages of the brain.

We used mini-chromosome maintenance protein 2 (MCM2) as a marker for proliferating cells because it is known to be directly involved in the cell cycle process through licensing DNA replication (Masai et al., 2010; Kuipers et al., 2011) and therefore marks proliferating regions (Maslov et al., 2007). Unlike other common markers, such as ph3 or Ki67, MCM2 is required for the initial cell cycling process (Stoeber et al., 2001). This allows the analysis of a broader spectrum of proliferating cells as compared to ph3 and gave a better signal than most Ki67 stainings. Regarding validity, MCM2 shows a good correlation with standard methods for *in vivo* proliferation analysis like

thymidine analog labeling (Maslov et al., 2004) with the advantage of being independent of cell cycle length which may alternate during development and stem cell population (Calegari and Huttner, 2003; Calegari et al., 2005). MCM2 is expressed in adult as well as in embryonal neural stem cells *in vivo* (Berg et al., 2019). Together, MCM2 is—although not often used—a well-characterized and established marker for proliferation analysis in brain development (von Bohlen und Halbach, 2011).

A large body of research during the late 1980s and 1990s explored the development of the two major catecholaminergic neurotransmitter systems in the mammalian brain. All these studies looked at these systems as developing neurotransmitter systems, but could not focus on the regulation of neurogenesis or brain development, since the knowledge of such regulatory functions of neurotransmitters was rather limited at that time. Consequently, dopaminergic innervation was studied mainly in the nigrostriatal and mesolimbic systems, and

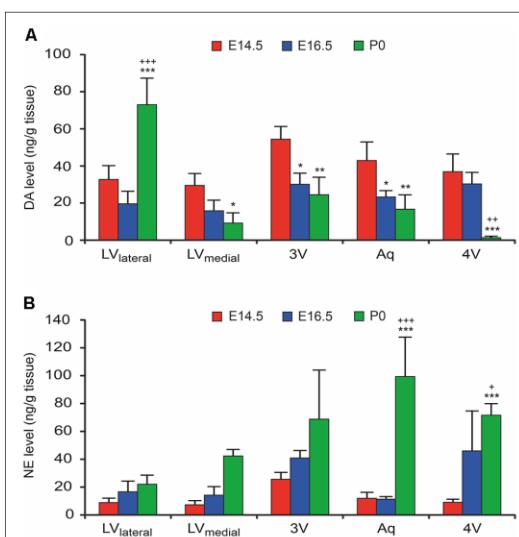

FIGURE 3 | Catecholamine levels in microdissected VZ/SVZ regions of the developing mouse brain (at developmental stages E14.5, E16.5, and P0). Catecholamine levels were measured in microdissected VZ/SVZ regions using an HPLC with electrochemical detection and normalized to tissue weight. **(A)** Dopamine (DA) levels were increasing in the VZ/SVZ of the LV lateral walls (LV_{lateral}), while they were continuously declining during development in the caudal VZ/SVZ regions. Two-way ANOVA with brain regions and developmental stages as fixed factors revealed that VZ/SVZ regions and stages had a significant interaction effect on DA levels ($P < 0.001$, $F\text{-value} = 13.3$) and significant differences among VZ/SVZ regions ($P < 0.001$, $F\text{-value} = 10.3$) and stages ($P < 0.001$, $F\text{-value} = 14.1$). **(B)** In contrast to DA, norepinephrine (NE) showed continuously increasing levels in the caudal (hindbrain) VZ/SVZ regions during development. Two-way ANOVA revealed that VZ/SVZ regions and stages had a significant interaction effect on NE levels ($P = 0.001$, $F\text{-value} = 4.3$) and significant differences among VZ/SVZ regions ($P = 0.003$, $F\text{-value} = 5.3$) and stages ($P < 0.001$, $F\text{-value} = 32.4$). P -values from post hoc tests with Bonferroni adjustment are * $P < 0.05$, ** $P < 0.01$ and *** $P < 0.001$ when compared to E14.5 and + $P < 0.05$, ++ $P < 0.01$ and +++ $P < 0.001$ when compared to E16.5 (only P -values among developmental stages are displayed for clarity; complete statistics in Supplementary Tables S2, S3). 3V, third ventricle; 4V, fourth ventricle; Aq, aqueduct; LV_{lateral}, lateral wall of the lateral ventricles; LV_{medial}, medial wall of the lateral ventricles.

noradrenergic innervation was investigated mainly preferentially in cortical areas and the hypothalamus (Coyle and Molliver, 1977; Levitt and Moore, 1979; Berger and Verney, 1984), but no data on catecholaminergic innervation of the VZ/SVZ as the main proliferating zone of the developing brain are available. Even though the two systems develop in parallel with increasing innervation of the VZ/SVZ in perinatal stages (between E16.5 and P0), we found different innervation patterns of the periventricular regions mainly containing the VZ/SVZ by the two catecholamines largely reaching the adult patterns at birth (P0): While the dopaminergic innervation focusses on the VZ/SVZ of the LV_{lateral} close to the striatum, the noradrenergic innervation omits the striatum

and the adjacent periventricular region but instead reaches the midbrain/hindbrain periventricular regions. These results closely fit data from previous studies showing noradrenergic innervation in the diencephalon surrounding the 3rd ventricle and dopaminergic innervation in the striatum adjacent to the LV_{lateral} between E13 and E15 (Olson and Seiger, 1972; Ribary et al., 1986; Tomasini et al., 1997). Of note, although the general patterns of catecholaminergic innervation levels match the adult situation already in the early postnatal period, brain catecholamine levels are much higher in the adult brain compared to perinatal stages due to further postnatal maturation of the two catecholaminergic systems (Berger and Verney, 1984; Ribary et al., 1986; Tomasini et al., 1997; Murrin et al., 2007).

The major catecholamines DA and NE are pleiotropic molecules and do not only play a pivotal role in synaptic neurotransmission but are also involved in brain maturation (Felten et al., 1982; Gustafson and Moore, 1987; Berger-Sweeney and Hohmann, 1997). Particularly NE is expressed during early embryonic development and regulates both the development of the respective neuronal population and the development of its various target areas including the cortex (Berger-Sweeney and Hohmann, 1997). Consistently, the NE system regulates the development of the Cajal-Retzius cells as the first cortical neurons and is thus considered to be involved in neuronal migration and laminar formation most likely via $\alpha 2$ adrenergic receptor signaling (Wang and Lidow, 1997; Naqui et al., 1999). All these studies applied lesions of the NE system during the early postnatal period and mainly addressed cortical development and in some cases also cerebellar development (for review see Berger-Sweeney and Hohmann, 1997; Saboory et al., 2020). A single study reporting the effects of severe prenatal lesioning of the NE system by the intrauterine 6-hydroxydopamine application at E17 revealed no major alterations in cortical morphology in adulthood but did not study other brain regions (Lidov and Molliver, 1982). Our data provide first morphological evidence to support putative pleiotropic effects of NE even during earlier stages of brain development mainly in the diencephalic region as one region with high periventricular NE innervation: we detected an inverse strong negative correlation of the proliferation capacity in the periventricular neurogenic regions with their NE levels ($r = -0.932$ for log-transformed counts of proliferating cells; $P < 0.001$), but not their DA levels. Though, a functionally relevant inhibitory effect of NE on stem cell proliferation within the periventricular regions during development still needs to be confirmed by future pharmacological and genetic studies. As warranted to show the functional importance of these findings, our data suggest potent inhibitory effects of NE on stem cell proliferation within the periventricular regions during development. Consistently, prenatal treatment of rats with β -adrenoceptor agonists at gestational days 17–20 results in decreased cell numbers in the fetal brain through cAMP production in target cells (Garofolo et al., 2003; Slotkin et al., 2003). This sensitive developmental stage closely corresponds to parallels the stage of increasing NE levels and decreasing cell proliferation within the mouse

Periventricular Catecholaminergic Innervation During Development

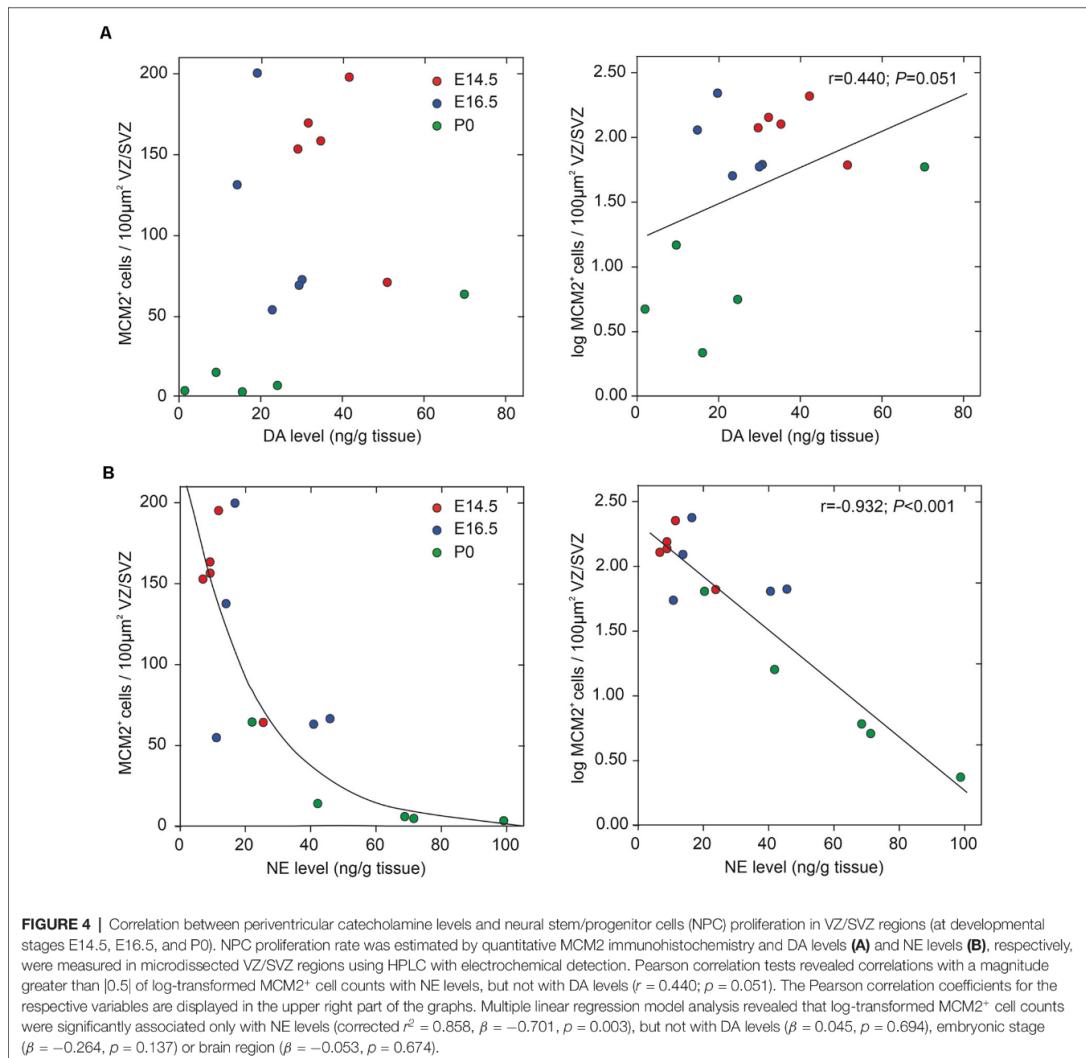

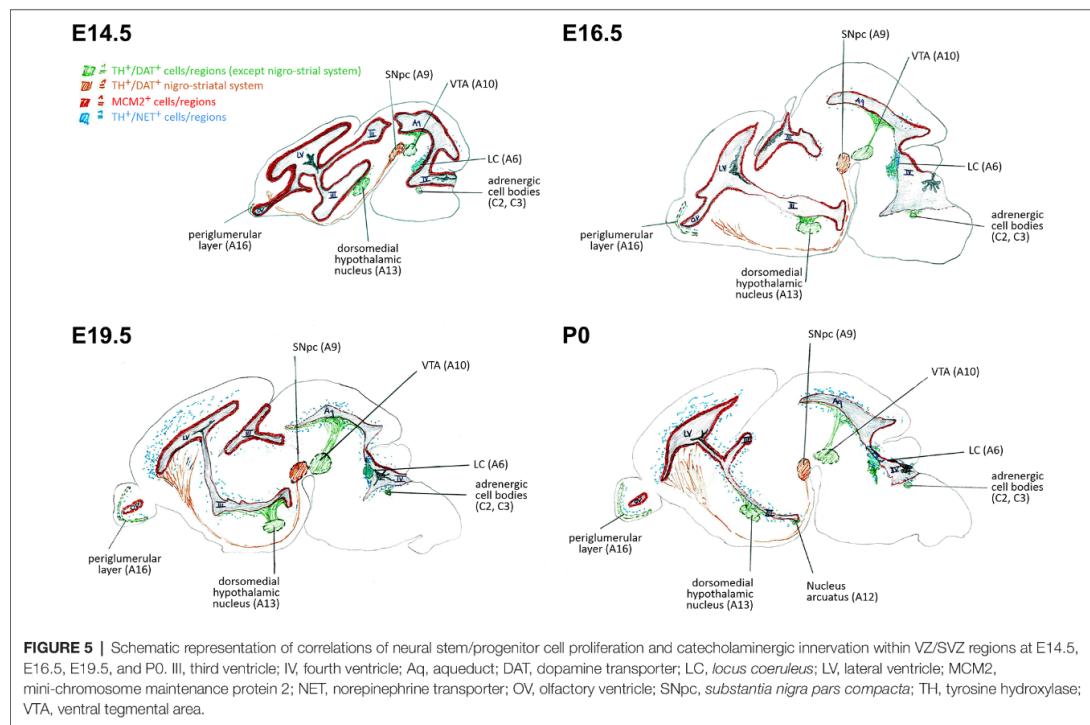

FIGURE 4 | Correlation between periventricular catecholamine levels and neural stem/progenitor cells (NPC) proliferation in VZ/SVZ regions (at developmental stages E14.5, E16.5, and P0). NPC proliferation rate was estimated by quantitative MCM2 immunohistochemistry and DA levels (**A**) and NE levels (**B**), respectively, were measured in microdissected VZ/SVZ regions using HPLC with electrochemical detection. Pearson correlation tests revealed correlations with a magnitude greater than 0.5 of log-transformed MCM2⁺ cell counts with NE levels, but not with DA levels ($r = 0.440; P = 0.051$). The Pearson correlation coefficients for the respective variables are displayed in the upper right part of the graphs. Multiple linear regression model analysis revealed that log-transformed MCM2⁺ cell counts were significantly associated only with NE levels (corrected $r^2 = 0.858, \beta = -0.701, p = 0.003$), but not with DA levels ($\beta = 0.045, p = 0.694$), embryonic stage ($\beta = -0.264, p = 0.137$) or brain region ($\beta = -0.053, p = 0.674$).

VZ/SVZ at E16.5 to P0. Unfortunately, there are no detailed brain morphology studies in genetic NE depleted mice (DbH knockout mice) available, most likely due to the almost 100% early postnatal mortality without indirect NE substitution during development (Thomas et al., 1995; Jin et al., 2004). The lethal phenotype without NE supplementation during crucial developmental stages however makes it impossible to accurately study embryonic/fetal brain development under NE depletion in this model. Nevertheless, these data in the fetal brain are in strong agreement with the inhibitory effects of NE on neural stem/progenitor cell proliferation within the periventricular regions of the adult mouse brain most likely

also mediated through direct stimulation of β -adrenoceptors (Weselek et al., 2020).

Together, the levels of the two major catecholamines DA and NE dramatically increased within the VZ/SVZ area of the developing brain between E16.5 and P0 with DA levels increasing in forebrain VZ/SVZs bordering the LV_{lateral} and NE levels raising in midbrain/hindbrain VZ/SVZs bordering the third ventricle, the aqueduct, and the fourth ventricle. Conversely, the number of proliferating cells of the VZ/SVZ areas dropped between E16.5 and E19.5 with a special focus on all VZ/SVZs outside the lateral ventricles leading to an inverse strong negative correlation of the proliferation capacity in the

periventricular neurogenic regions with their NE levels. These results are backed by our recent findings of direct negative effects of NE on the proliferation of adult periventricular neural stem/progenitor cells (Weselek et al., 2020). Our data provide the first framework to further study the potential functional importance of catecholamines—particularly NE—in regulating neural stem and progenitor cell proliferation and differentiation during mammalian brain development.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The animal study was reviewed and approved by Animal Welfare Committee at the Technische Universität Dresden and Landesdirektion Sachsen (governmental authorities).

AUTHOR CONTRIBUTIONS

GW, AH and AS substantially contributed to the study concept and design, acquisition of data, analyzing of data, interpretation of data, drafting and finalizing the manuscript. MG and CH substantially contributed to the acquisition of

data, analyzing of data and interpretation of data. MF and FM substantially contributed to the interpretation of data, drafting and finalizing the manuscript. All authors critically revised the final manuscript.

FUNDING

This work was supported by the Deutsche Forschungsgemeinschaft (DFG) through the Collaborative Research Centres CRC 655 “Cells into Tissue” (project A23). MF was supported by the CRC 1270 “Electrically Active Implants” (DFG; SFB 1270/1-299150580) through the rotation position program for clinician scientists. AH was supported by the Hermann and Lilly Schilling-Stiftung für medizinische Forschung im Stifterverband.

ACKNOWLEDGMENTS

We would like to thank Sylvia Kanzler, Andrea Kempe, and Cornelia May for their technical support.

Supplementary Material

1 Supplementary Figures

Supplementary Figure S1: Catecholamine levels in microdissected periventricular regions of the adult mouse brain (8 to 12 weeks). Catecholamine levels were measured in microdissected periventricular regions using a HPLC-based method and normalized to tissue weight. **(A)** Dopamine (DA) levels were high in the subventricular zone (SVZ) of the lateral walls of the lateral ventricles (LV_{lateral}), but low in medial wall of the LV (LV_{medial}) as well as the caudal periventricular regions bordering the 3rd ventricle (3V), the aqueduct and the 4th ventricle (4V) (n=4). **(B)** In contrast to DA, norepinephrine (NE) showed high levels only in the caudal (midbrain/hindbrain) periventricular regions (n=3-4). Data on NE levels from SVZ, 3V and Aq are from Weselek and co-workers (Weselek, Keiner et al. [2020]. Stem Cells, doi: 10.1002/stem.3232).

2 Supplementary Tables

Supplementary Table S1A,B: Statistics determined for the amount of proliferative cells within the VZ (MCM2^+ nuclei per $100\mu\text{m}^2$) in the different regions and developmental stages (Figure 1). Two-way ANOVA with *post-hoc* t-test and Bonferroni adjustment with VZ regions and developmental stages as fixed factors revealed that VZ regions and stages had a significant interaction effect on MCM2^+ cells per $100\mu\text{m}^2$ ($P<0.001$, F-value=5.7) and significant differences among VZ regions ($P<0.001$, F-value=17.1) and stages ($P<0.001$, F-value=95.0). Displayed are the Bonferroni-adjusted P -values. **(A)** Significances among the different VZ regions. **(B)** Significances among the developmental stages. Bold values indicate significant differences.

5 Diskussion

5.1 Kurzzeitige Sauerstoffapplikation führt zu beschleunigter Neurogenese

Die vorgelegten Daten zeigen, dass kurzzeitige maternale Hyperoxie die Neurogenese durch vermehrte Zellteilungen der neuronalen Vorläuferzellen beschleunigt sowie temporär zu einem vergrößerten Kortex führt (Markert and Storch 2022). Die Anwendung maternaler Hyperoxie über 48 h von Embryonalstadium (E) 14,5 bis E16,5 ist dabei von entscheidender Bedeutung, da die Applikationen >48 h, die Applikation zu früheren Zeitpunkten oder die chronische intermittierende Applikation zu gegenteiligen oder keinen Effekten führt (Wagenfuhr et al. 2015, Lange et al. 2016, Markert et al. 2020). Der aufgrund kurzzeitiger maternaler Hyperoxie vergrößerte Kortex ist spezifisch durch eine Zunahme an Ctip2⁺ Schicht V-Neuronen charakterisiert, deren Anzahl im Postnatalstadium (P) jedoch normalisiert wird (siehe Abbildung 5). Die Normalisierung erfolgt durch Beteiligung aktiver Mikroglia, welche die überschüssigen, nicht-apoptotischen Ctip2⁺ Neurone und apikal verbliebene überschüssige Vorläuferzellen phagozytieren und deren reguläre Zellzahl wiederherstellen. Daher stellen Mikroglia Schlüsselfaktoren zur Wiederherstellung einer normalen kortikalen Schichtung nach maternaler Hyperoxie dar, wobei sie diese Funktion möglicherweise auch im Rahmen der physiologischen Gehirnentwicklung erfüllen.

Zur Erforschung der Effekte von Sauerstoff auf die Neurogenese wurde das etablierte murine Modell mit maternaler Hyperoxie von E14,5 bis E16,5 zurand gezogen, welches spezifisch Zellen der subventrikulären Zone (SVZ) zu erhöhter Proliferation anregt (Wagenfuhr et al. 2015, Wagenfuhr et al. 2016). Trotz eines in diesem Modell vergrößerten Kortex, kann Hyperoxie in der Gehirnentwicklung zu neurologischen Beeinträchtigungen führen (Deulofeu et al. 2006, Gerstner et al. 2008, Porzionato et al. 2015, Ramani et al. 2018). Daher stellte sich zunächst die Frage, ob maternale Hyperoxie zur persistierenden Effekten führt, wobei gezeigt werden konnte, dass aktive Mikroglia kurz nach Geburt für eine Normalisierung der Anzahl an Neuronen in Schicht V des Kortex sorgen, sodass an P3,5 zwischen behandelten Tieren und den Kontrolltieren kein Unterschied mehr in der Morphologie des Gehirns feststellbar ist. Für Mikroglia ist zwar bekannt, dass auch nicht-apoptotische Vorläuferzellen und Neurone in der VZ und SVZ phagozytieren, bevor sie ab

E = Embryonalstadium; P = postnatales Stadium; VZ = ventrikuläre Zone; SVZ = subventrikuläre Zone; IZ = Intermediärzone; SKP = subkortikale Platte; KP = kortikale Platte; VI - I = kortikalnen Schichten sechs bis eins. Erstellt mit BioRender.com.

E16 die kortikale Platte kolonisieren (Cunningham et al. 2013, Squarzoni et al. 2014), dass sie diese Funktion allerdings auch in der kortikalen Platte weiter ausfüllen und dabei physiologisch die Anzahl an Ctip2⁺ Zellen und wahrscheinlich auch die Anzahl Satb2⁺ Zellen regulieren ist bislang gänzlich unerforscht. Dazu passend konnte bereits gezeigt werden, dass Mikroglia im Kortex bis P3 ihren amöboiden aktiven Zustand beibehalten und erst nach P3 ihr typisches verzweigtes Aussehen bekommen sowie durch Ausschüttung trophischer Faktoren das Überleben von Schicht V Neuronen ermöglichen (Hristova et al. 2010, Ueno et al. 2013). Um diesen Mechanismus weiter aufzuklären, sind Folgestudien notwendig, in welchen Mikroglia gezielt ausgeschaltet werden und die Auswirkungen auf die Regulation der Neurogenese in den jeweiligen kortikalen Schichten untersucht wird. Ein entsprechender Zusammenhang könnte die Pathologie von entwicklungsbiologischen neurologischen Störungen erklären, bei denen sowohl Mikroglia als auch Schicht V Neurone beteiligt sind (Mi et al. 2019, Kolomeets and Uranova 2019, Uranova et al. 2020, Uranova, Vikhreva and Rakhmanova 2021). In diesem Kontext ist aktuell noch nicht

bekannt, ob und inwieweit diese neuropathologischen Alterationen auch mit messbaren Verhaltensänderungen/-auffälligkeiten assoziiert sind. Ein erstes Indiz dazu liefert die initiale immunhistochemische Analyse von VGlut2⁺ Synapsen, welche ebenfalls von maternaler Hyperoxie betroffen sind und im Anschluss normalisiert werden (Nakamura et al. 2007). Ohne weitere Studien können Auswirkungen auf das Verhalten oder kognitive Störungen jedoch nicht ausgeschlossen werden. Sowohl das Verhalten bei physiologischer Entwicklung nach maternaler Hyperoxie, sowie das Verhalten und die Gehirnmorphologie bei fehlender Normalisierung, etwa durch Mikrogliadepletion, sollten Gegenstand zukünftiger Forschung sein.

Nachdem in einer initialen Studie sowie in Vorarbeiten der Arbeitsgruppe um Prof. Storch gezeigt werden konnte, dass maternale Hyperoxie nicht-invasiv die Gehirnentwicklung beeinflussen kann (Wagenfuhr et al. 2015, Markert and Storch 2022), wurde in einer Folgestudie untersucht, inwieweit dieser Effekt durch ein chronisches Applikationsschema ausgedehnt oder verändert werden kann (Markert et al. 2020). Dazu wurden trächtige C57BL/6J Mäuse von E5 bis E16 intermittierend unter Hyperoxie gehalten. Die Unterbrechung der maternalen Sauerstoffbehandlung diente dabei als Erholungsphase, da eine Hyperoxie von >72 h mit schweren Belastungen der Muttertiere einhergeht. Es wurde gezeigt, dass chronische intermittierende maternale Hyperoxie zu einer Reduktion von Pax6⁺ neuronalen Vorläuferzellen und einer abnormalen kortikalen Schichtung führt, welche nicht durch Apoptose oder veränderte Angiogenese bedingt sind. Die Effekte sind dabei konträr zur kurzzeitigen maternalen Hyperoxie (48 h), ähneln aber einer maternalen Hyperoxie über 72 h, bei welcher ebenfalls eine Reduktion ventrikulärer Vorläuferzellen gezeigt werden konnte (Wagenfuhr et al. 2015, Lange et al. 2016, Markert and Storch 2022). Aus *in vitro* Studien ist bereits bekannt, dass chronisch hypoxischer bzw. physiologischer Sauerstoffpartialdruck um 5%, ähnlich wie auch in den neurogenen Nischen vorkommend, den Erhalt von Stammzellen fördern können, wohingegen normaler Sauerstoffpartialdruck um 20 % eher zu Differenzierung führt (Studer et al. 2000, Storch et al. 2001, Erecinska and Silver 2001, Santilli et al. 2010, Braunschweig et al. 2015). Die in den vorliegenden Studien unterschiedlichen Auswirkungen von Sauerstoff in Abhängigkeit von Intensität bzw. Dauer lassen jedoch einen dynamischen Prozess vermuten, in welchem eine kurzzeitige maternale Hyperoxie die Proliferation fördert, langfristig jedoch zu erhöhter Differenzierung führt. Entsprechend könnte die chronische intermittierende Sauerstoffbehandlung initial zu einer kurzfristigen Zunahme der Proliferation, über die Dauer der Behandlung hinweg jedoch zur Zunahme der

Diskussion

Differenzierung geführt haben, sodass zum Analysezeitpunkt insgesamt weniger Pax6⁺ Zellen und verringelter Mitoseaktivität nachgewiesen werden konnten. Wie in Markert et al. 2020 gezeigt, wäre der resultierende Kortex in seiner Dicke unverändert, würde jedoch aufgrund des Mangels an Pax6⁺ Zellen eine abnormale Schichtung aufweisen (Tuoc et al. 2009, Georgala, Manuel and Price 2011). Passend dazu befinden sich mehr Zellen in den chronologisch frühen Schichten des Kortex (Tbr1⁺ Zellen in inneren Schicht VI), dafür weniger in den darauffolgenden Schichten (Satb2⁺ Zellen in den äußeren Schichten). Andererseits können spezifische Effekte ausgelöst durch das intermittierende Applikationsschema oder eingeschränkte Migration der Neurone nicht ausgeschlossen werden (Talamillo et al. 2003, Tsai et al. 2005, Nishimura et al. 2010). Zudem ist nicht klar, ob die morphologischen Veränderungen zu späteren kognitiven Beeinträchtigungen führen. So konnten in einer klinischen Pilotstudie bezüglich chronischer intermittierender maternaler Applikation von Sauerstoff zur Therapie des hypoplastischen Linksherzsyndrom bei Kindern im Alter von 6 Monaten zwar ein verringelter Kopfumfang, jedoch keine kognitive Beeinträchtigung festgestellt werden (Edwards et al. 2018). Zur Untersuchung, inwieweit regulatorische Effekte wie in Markert&Storch (2022) auch hier zu einer späteren Normalisierung führen, müssen weitere Studien durchgeführt werden.

5.2 Regulation der fetalen Neurogenese durch Noradrenalin

Zur Untersuchung der Effekte von Noradrenalin (NA) und Dopamin (DA) auf die ventrikuläre und subventrikuläre Zonen (VZ/SVZ) im sich entwickelnden Gehirn wurden der Katecholamingehalt und die Anzahl an proliferierenden Zellen zu definierten Zeitpunkten ermittelt. Der NA Gehalt steigt dabei im Verlauf der Entwicklung in allen untersuchten Hirnregionen an und korreliert invers mit der Anzahl an proliferierenden Zellen. DA hingegen zeigt ein differenziertes Bild im Verlauf der Gehirnentwicklung und korreliert nicht mit der Anzahl an proliferierenden Zellen entlang der Ventrikel. Die Studie postuliert daher eine physiologische Funktion von Noradrenalin als Hemmstoff für die Proliferation von Stammzellen während der Gehirnentwicklung. Eine experimentelle Evidenz für diesen Effekt steht allerdings noch aus.

Diese Daten sind konsistent mit einer vorherigen Studie an adulten Tieren, in welcher der NA-Gehalt im Gehirn pharmakologisch beeinflusst wurde und ebenfalls zu einer Hemmung der adulten Neurogenese entlang der Ventrikel führte (Weselek et al. 2020). Im Detail konnte gezeigt werden, dass die Degeneration der NA produzierenden LC Neurone

zu vermehrter Proliferation von Zellen entlang der Ventrikalachse führt und dieser Effekt durch exogene Zugabe von NA reversibel ist. Zudem führte die exogene NA Zugabe in der SVZ adulter Tiere, welche physiologischerweise wenig NA beinhaltet, zu einer Hemmung der adulten Neurogenese. Ergänzend hierzu konnte in der aktuellen Studie gezeigt werden, dass die Hemmung der periventrikulären Neurogenese nicht auf die adulte Situation begrenzt ist, sondern bereits physiologisch die Gehirnentwicklung beeinflusst. Durch Nutzung des Stammzellmarkers MCM2 (*Mini-chromosome maintenance protein 2*), einem etablierten Proliferationsmarker *in vivo*, konnten wir die perinatal anhaltende Neurogenese über den Zeitverlauf E14,5, E16,5, E19,5 und P0 analysieren (Stoeber et al. 2001, von Bohlen und Halbach 2011). Da MCM2 beinahe über den gesamten Zellzyklus hinweg exprimiert wird, ist er unabhängig von der sich während der Gehirnentwicklung ändernden Zellzykluslänge (Calegari and Huttner 2003, Calegari et al. 2005). Die erhaltenen Daten sind daher robust, um eine Aussage über die generelle Neurogenese zu treffen.

Zur Korrelation der Neurogenese mit dem Gehalt an Katecholaminen wurde der NA- und DA-Gehalt mit Hochleistungsflüssigkeitschromatographie (HPLC) analysiert, dem Goldstandard für quantitative Katecholaminmessungen. Beide Katecholamine sind seit Jahrzehnten in ihrer Rolle als Neurotransmitter detailliert beschrieben (Berridge and Waterhouse 2003, Greengard, Allen and Nairn 1999, Ruitenberg et al. 2021, Cools et al. 2022). Weniger erforscht sind dagegen die Effekte von NA und DA auf die Regulation der Neurogenese bzw. der Gehirnentwicklung (Felten, Hallman and Jonsson 1982, Gustafson and Moore 1987). Bislang ist bekannt, dass NA die adulte hippocampale Neurogenese via β_2 -Adrenorezeptoren anregt (Bortolotto et al. 2019), während die Migration und Schichtung des Kortex via α_2 -Adrenorezeptoren, welche pränatal im Bereich der VZ stark exprimiert werden, sowie des Kleinhirns über andere Rezeptoren beeinflusst werden und unter pathologischen Bedingungen zu späteren Verhaltensstörungen führen (Naqui et al. 1999, Djatchkova-Podkletnova and Alho 2005, Wang and Lidow 1997, Lidow and Rakic 1994, Wang et al. 2002). Die meisten funktionellen Studien wurden jedoch mittels Läsion des dopaminerigen bzw- noradrenergen Systems durch 6-Hydroxydopamin und maßgeblich in postnatalen Entwicklungsstadien durchgeführt, sodass konkrete Aussagen der Katecholamineffekte auf die zeitige Neurogenese aufgrund der Toxizität des Agens nicht möglich waren (Bear and Singer 1986, Osterheld-Haas, Van der Loos and Hornung 1994). Ansätze mit transgenen Mäuse, in welchen die NA synthetisierende Dopamin- β -Hydroxylase ausgeschaltet wurde, waren ebenso wenig geeignet, da NA Mangel während der Entwicklung letal ist und die Tiere mit NA-Vorläufersubstanzen substituiert werden

Diskussion

mussten (Thomas, Matsumoto and Palmiter 1995, Shepard et al. 2015). Die Daten aus (Fauser et al. 2020) zeigen daher zum ersten Mal einen Zusammenhang zwischen NA und der periventrikulären embryonalen Neurogenese in Form einer starken inversen Korrelation. DA hingegen scheint keine Einfluss auf selbige zu haben. Ein ähnlicher Effekt konnte in einem Mausmodell mit Noradrenalinüberschuss gezeigt werden, in welchem weniger Neurone während der Entwicklung auftraten, obgleich verschiedenen Limitationen wie Begrenzung der Analyse auf nur eine Neuronenart und zusätzlich Serotoninüberschuss den Vergleich limitieren (Pronina et al. 2007). Auch Untersuchungen, in denen die Wirkung von NA mittels Injektion von β -Adrenorezeptoragonisten in Ratten (E17 bis E20) nachgeahmt wurde, zeigen eine Reduktion des DNA-Gehalts und somit der Zellzahl im Gehirn und reflektieren dabei nahezu das gleiche Stadium der Gehirnentwicklung wie in den von uns gezeigten Daten (Garofolo et al. 2003). Dennoch sind weitere funktionelle Untersuchungen hinsichtlich etwaiger späterer Verhaltensänderungen sowie insbesondere detailliertere Analysen der Beteiligung der verschiedenen Rezeptorsubtypen notwendig, um den Mechanismus von insbesondere NA auf die Gehirnentwicklung besser zu verstehen (Dygalo, Shishkina and Milova 1993, Dygalo et al. 2000). Trotz dieser Limitationen legen die Daten zum Einfluss von NA auf die fetale Hirnentwicklung nahe, dass NA eine inhibitorische Wirkung auf die Proliferation neuronaler Stammzellen in VZ/SVZ aufweist und diese eine entscheidende Rolle sowohl während des Verlaufs der Gehirnentwicklung, als auch bei der adulten Neurogenese spielt.

6 Zusammenfassung

Die Entstehung des Gehirns ist ein streng regulierter und komplexer Prozess, welcher sowohl unter physiologischen, als auch pathologischen Bedingungen bis dato nur ansatzweise verstanden ist. Um dieses grundlegende Wissen zu erweitern, wurden in der vorliegenden Arbeit zwei Parameter untersucht: Sauerstoff, als ein wichtiger Signalfaktor innerhalb der Entwicklung und Katecholamine, welche neben ihrer Funktion als Neurotransmitter als trophische Faktoren die Neurogenese mit regulieren. Als Modellorganismen dienten zeitlich exakt verpaarte C57BL/6 Mäuse, welche zur Untersuchungen des Effektes von erhöhtem Sauerstoffpartialdruck von Embryonalstadium (E) 14,5 bis E16,5 in 75 % Sauerstoff oder von E5,5 bis E16,5 im 24 Stundenintervall (24 h 75 % Sauerstoff / 24 h Normalluft) gehalten wurden. Zu jeweils verschiedenen Zeitpunkten der Entwicklung erfolgte die Präparation der fetalen Gehirne und Analyse dieser mittels immunhistochemischer Färbungen bzw. HPLC der Katecholamine. Der Einflussfaktor Sauerstoff zeigte dabei ein differenziertes Bild: während die zeitige intervallartige Sauerstoffbehandlung zu verringriger Zellteilung führt, ruft die kurzzeitige Sauerstoffbehandlung über 48 h vermehrte Zellteilung und größere Kortizes aufgrund einer vergrößerten neokortikalen Schicht V hervor. Spannenderweise sorgen kurz nach Geburt aktive Mikroglia dafür, dass diese Schicht V wieder auf das Level un behandelter Tiere normalisiert wird. Die kurzzeitige Sauerstoffbehandlung stellt daher eine leicht applizierbare, nicht-invasive Behandlungsmöglichkeit dar, um möglicherweise fetalen kortikalen Unterentwicklungen entgegenzuwirken, ohne einen persistierenden Überschuss an Neuronen hervorzurufen. Die Analyse der zeitlich parallel ablaufenden dopaminergen und noradrenergen Innervation der neurogenen Nischen im fetalen Mausgehirn ergab, dass Noradrenalin, nicht jedoch Dopamin invers mit der fetalen Neurogenese bzw. invers mit der Anzahl an proliferierenden Zellen korreliert. Noradrenalin ist daher ein potentieller Inhibitor der Neurogenese, wie es im adulten Mausgehirn beschrieben wurde. Experimentell muss dieser Effekt jedoch noch bestätigt werden. Sowohl Sauerstoff als auch Noradrenalin scheinen grundlegende physiologische Faktoren darzustellen, welche die Neurogenese durch direkte Beeinflussung der Proliferation neuronaler Stammzellen steuern. Diese Erkenntnis dient als Basis dafür, die Rolle beider Parameter unter pathologischen Bedingungen zu untersuchen sowie durch therapeutische Manipulation eine adäquate Entwicklung des Gehirns unter pathologischen Bedingungen zu ermöglichen.

Summary

Brain development is a tightly regulated and complex process, which is only partially understood to date, both under physiological and pathological conditions. In order to expand this basic knowledge, two parameters were investigated in the present study: oxygen representing an important signaling factor during development and catecholamines, which, in addition to their function as neurotransmitters, are also associated with neurogenesis as trophic factors. The model organisms were C57BL/6 mice mated exactly in time. They were kept either in 75 % oxygen from embryonic stage (E) 14.5 to E16.5 or in a 24 h interval (24 h 75 % oxygen / 24 h normal air) from E5.5 to E16.5 to investigate the effect of elevated oxygen levels. At different time points of development, fetal brains were prepared and analyzed by immunohistochemical stainings or HPLC of the catecholamines. The parameter oxygen showed a differentiated picture: while the temporal interval-like oxygen treatment leads to reduced cell division, the short-term oxygen treatment over 48 h causes increased cell division and larger cortices due to an enlarged layer 5. Excitingly, shortly after birth, active microglia ensure that this layer 5 is normalized back to the level of untreated animals. Short-term oxygen treatment is therefore an easy-to-apply, non-invasive treatment option to potentially counteract fetal cortical underdevelopment without causing a persistent excess of neurons. Analysis of temporally parallel dopaminergic and noradrenergic innervation of the neurogenic niches in the fetal mouse brain revealed that noradrenaline, but not dopamine, inversely correlates with fetal neurogenesis or inversely correlates with the number of proliferating cells. Norepinephrine is therefore a potential inhibitor of neurogenesis, as has been described in the adult mouse brain. Experimentally, however, this effect remains to be confirmed.

Together, both oxygen and noradrenaline seems to represent fundamental physiological factors that control neurogenesis by directly influencing the proliferation of neural stem cells. Knowledge of this provides the basis for investigating the role of both parameters under pathological conditions as well as for enabling adequate brain development during pathological conditions through therapeutic manipulation.

8 Abkürzungen

BrdU	Bromdesoxyuridin
brGZ	basale radiale Gliazelle
DA	Dopamin
E	Embryonalstadium
EdU	Ethyndesoxyuridin
HIF	Hypoxie induzierender Faktor
HPLC	Hochleistungs-Flüssigkeitschromatographie; <i>High-Performance Liquid Chromatography</i>
iVZ	Intermediäre Vorläuferzelle
LC	Locus coeruleus
P	Postnatalstadium
rGZ	Radiale Gliazelle
RRID	Identifikatoren für Forschungsressourcen; <i>Research Resource Identification</i>
SN	Substantia nigra
SVZ	Subventrikuläre Zone
TBST	Tris gepufferte Salzlösung mit TWEEN 20; Tris buffered saline with TWEEN 20
VGlut2	Vesikulärer Glutamattransporter 2
VTA	Ventrales tegmentales Areal
VZ	Ventrikuläre Zone

11 Appendix

Danksagung

Mein herzlicher Dank gilt allen voran Prof. Dr. Storch für die exzellente Betreuung, für die wann immer nötige Unterstützung und für die vielen Erfahrungen und Ratschläge, die Sie mit mir sowie der Arbeitsgruppe teilen. Die vielen wissenschaftlichen – sowie auch nicht-wissenschaftlichen – Gespräche waren stets Inspiration zu neuen Zielen und haben mich in der Wissenschaft wie auch menschlich weitergebracht.

Auch möchte ich mich bei Prof. Dr. Dr. Hermann, Dr. Francia Molina, Dr. Kathrin Badstübner-Meeske, sowie Dr. Grit Weselek bedanken, durch deren jeweilige Leitung des Labors ich perfekte Bedingungen für meine Experimente und die Anfertigung meiner Promotionsschrift vorgefunden habe.

Ein sehr großer Teil des Dankes gilt dem gesamten Laborteam des FEN, sowie auch dem AKOS, für die stets tolle Stimmung. Die gemeinsamen Mittagessen, Ausflüge und Feiern waren immer Highlights. Insbesondere seien dabei Uta Naumann für ihre unglaubliche Hilfe bei allen denkbaren Angelegenheiten und besonders für ihr sonniges Gemüt, Dr. Mareike Fauser für die vielen Tipps, Ratschläge, Hilfestellungen und Diskussionen und Jennifer Lanto für die tolle Stimmung im Büro und die wunderbare Freundschaft erwähnt. Besonders dankbar bin ich Anna-Maria Pielka für all die gemeinsame Zeit, egal ob Leid oder Freude, egal ob Dresden, Malta oder Rostock, mit und dank dir hat die ganze Arbeit viel mehr Spaß gemacht und all die Experimente die nicht geklappt haben waren nur halb so schlimm. Auch wenn wir nicht mehr zusammen arbeiten kann ich heute wie auch damals zwei Wochen nach Beginn unserer Promotion sagen: „ich bin echt froh, dass ich dich als Kollegin habe“!

Nicht zuletzt danke ich auch meiner Familie, welche mich trotz meiner häufigen Abwesenheit jederzeit unterstützt hat. Von Schule, Bund, Studium bis zur Promotion, ihr seid im Zweifel immer für mich da. Dank euch war dies alles möglich und ich bin jedes Mal froh, wenn ich mal wieder ein Wochenende zuhause bin.

Selbstständigkeitserklärung zur Promotionsschrift

Ich versichere hiermit, dass ich die vorliegende Arbeit mit dem Thema „Einfluss von Sauerstoff und Katecholaminen auf die fetale kortikale Entwicklung der Maus“ selbstständig verfasst und keine anderen Hilfsmittel als die angegebenen benutzt habe. Die Stellen, die anderen Werken dem Wortlaut oder dem Sinn nach entnommen sind, habe ich in jedem einzelnen Fall durch Angabe der Quelle kenntlich gemacht.

Meine Anteile an den in die Promotionsschrift eingegangenen Veröffentlichungen sind im Folgenden aufgelistet:

- Hyperoxygenation during mid-neurogenesis accelerates cortical development in the fetal mouse brain
 - Planung und Durchführung der Versuche
 - Erhebung, Auswertung und Interpretation aller Daten
 - Erstellung, Finalisierung und Revision des Manuskripts
- Chronic maternal hyperoxygenation impairs cortical development by inhibition of Pax6⁺ apical progenitor cell proliferation
 - Planung und Durchführung der Versuche
 - Erhebung aller Daten, außer:
 - immunhistochemische Färbung NeuN
 - Messung kortikale Dicke
 - Auswertung und Interpretation aller Daten
 - Erstellung, Finalisierung und Revision des Manuskripts
- Catecholaminergic Innervation of Periventricular Neurogenic Regions of the Developing Mouse Brain
 - Interpretation aller Daten
 - Finalisierung und Revision des Manuskripts

Ich erkläre hiermit weiterhin, dass ich meine wissenschaftlichen Arbeiten nach den Prinzipien der guten wissenschaftlichen Praxis gemäß der gültigen „Regeln zur Sicherung guter wissenschaftlicher Praxis und zur Vermeidung wissenschaftlichen Fehlverhaltens“ an der Universitätsmedizin Rostock angefertigt habe.

Familienstand: Ledig

Forschungsschwerpunkte

Fetale kortikale Neurogenese

Effekte von Sauerstoff auf die Neurogenese

Tiefe Hirnstimulation im Kleintiermodell

Ausbildung und akademische Grade

Promotion Avisierte Einreichung der Dissertation 2022

Master of Science Medizinische Biotechnologie, 2014, Universität Rostock,
Gesamtnote: 1,6

Thema der Masterarbeit: „Effekte des M1-Proteins von *Streptococcus pyogenes* auf humane mesenchymale Stammzellen“ Note: 1,0

Bachelor of Science Molekulare Biotechnologie, 2012, Hochschule für angewandte Wissenschaften Zittau/Görlitz, Gesamtnote: 1,8

Thema der Bachelorarbeit: „Untersuchungen zur Wirkung der Bioresonanztherapie auf Zellkulturen“ Note: 1,3

Abitur 2007, Werner-von-Siemens-Gymnasium Großenhain,
Gesamtnote: 2,3

Berufserfahrung

- seit 2022 Bestelltes Mitglied des Tierschutzausschusses, Universitätsmedizin Rostock
- seit 2021 Labormanager, Forschungslabor Experimentelle Neurologie, Klinik und Poliklinik für Neurologie, Universitätsmedizin Rostock
- seit 2020 Stellvertretende Leitung der Tierhaltung, Klinik und Poliklinik für Neurologie, Universitätsmedizin Rostock
- seit 2016 Wiss. Mitarbeiter im Forschungslabor Experimentelle Neurologie, Klinik und Poliklinik für Neurologie, Universitätsmedizin Rostock
- 2014 - 2015 Wiss. Mitarbeiter im Institut für Zellbiologie, Universitätsmedizin Rostock
- 2011 - 2012 Wiss. Mitarbeiter am Fraunhofer-Institut für Organische Elektronik, Elektronenstrahl- und Plasmatechnik in Dresden

Tagungen

- 2021 „Research Day of the Department of Neurology“, Universitätsmedizin Rostock, Klinik und Poliklinik für Neurologie.
Vortrag: „Oxygen as a regulator of brain development“
- 2018 Symposium „The many faces of Parkinson’s disease - motor and non-motor symptoms from prodromal to advanced disease stages“, Universitätsmedizin Rostock, Klinik und Poliklinik für Neurologie
Poster: „Prolonged maternal hyperoxygenation affects proliferation in the developing mouse brain“

Forschungsförderung

- 2021 - GfN-MV **Antrag auf der Forschungsförderung** durch die Gesellschaft für Nervenheilkunde M/V zum Thema „Physiologische Entwicklung des Gehirns durch aktive Mikroglia“ (bewilligt)

- 2020 - FORUN **FORUN-Antrag** auf Forschungsförderung durch die Universitätsmedizin Rostock (abgelehnt: fehlende Promotion)
- 2019 - DFG Maßgebliche Beteiligung am DFG Großgeräteantrag: **Konfokales Laser Scanning Mikroskop LSM 900 mit AiryScan** (bewilligt)
- 2018 - EFRE Maßgebliche Beteiligung am Wissenschaftliche-Geräte-Antrag für eine **Glove-Box** sowie für ein **Kryomikrotom** des Europäischen Fonds für regionale Entwicklung (beide bewilligt)
